Abstract

This paper evaluates the global welfare impact of China's trade integration and technological change in a quantitative Ricardian-Heckscher-Ohlin model implemented on 75 countries. We simulate two alternative productivity growth scenarios: a "balanced" one in which China's productivity grows at the same rate in each sector, and an "unbalanced" one in which China's comparative disadvantage sectors catch up disproportionately faster to the world productivity frontier. Contrary to a well-known conjecture (Samuelson 2004), the large majority of countries in the sample, including the developed ones, experience an order of magnitude *larger* welfare gains when China's productivity growth is biased towards its comparative disadvantage sectors. We demonstrate both analytically and quantitatively that this finding is driven by the inherently multilateral nature of world trade. As a separate but related exercise we quantify the worldwide welfare gains from China's trade integration.

1 Introduction

The pace of China's integration into world trade has been nothing short of breathtaking. Figure 1(a) plots inflation-adjusted Chinese exports between 1962 and 2007, expressed as an index number relative to 1990. The value of Chinese exports has increased by a staggering factor of 12 between 1990 and 2007, far outpacing the 3-fold expansion of overall global trade during this period. Equally remarkable is the extent to which the emergence of Chinese exports is global in nature. Figure 1(b) reports the share of China in the total imports of all major world regions. The expansion of Chinese exports proceeded at a similar pace all over the world: in all the major regions, the share of imports coming from China currently stands at about 10%, with the exception of East and South Asia, for which it is 15%. China is a global presence, penetrating all world regions about equally.

Naturally, such rapid integration and growth leads to some anxiety. In developed countries, a common concern is that China's growth will be biased towards sectors in which the developed world currently has a comparative advantage. In a two-country setting, a well-known theoretical result is that a country can experience welfare losses when its trading partner becomes more similar in relative technology (Hicks 1953, Dornbusch, Fischer and Samuelson 1977, Ju and Yang 2009). Samuelson (2004) brought up this theoretical possibility for the growth of China in particular, and thus we refer to it as the *Samuelson conjecture*.

This paper explores both qualitatively and quantitatively the global welfare consequences of different productivity growth scenarios in China. We first show analytically that the intuitive two-country result does not survive in a setting with more than two countries. Greater similarity in China's relative sectoral technology to that of the United States *per se* does not necessarily lower United States' welfare. Rather, what drives welfare changes in the United States is how (dis)similar China becomes to an appropriately input-and-trade-cost-weighted average productivity of the United States and all other countries serving the United States market. In a multi-country world, third-country effects are of first-order importance for evaluating the impact of changes in relative technology in one country on both itself and its trading partners.

To derive these results, we set up a simple multi-sector, multi-country Eaton and Kortum (2002) model, and examine how changes in relative sectoral productivities in an individual country – which we think of as China – affect both its own welfare and the welfare of its trading partners. The gains to the U.S. consumers from access to Chinese goods are lowest when the relative prices at which China can supply the U.S. market are most similar to the relative prices facing U.S. consumers in the absence of China. With only two countries, those relative prices are the U.S. autarky prices, and thus welfare is lowest when relative sectoral productivity is identical in the two countries. This is a variant of Samuelson (2004)'s result in a setting in which the sectors

have an Eaton and Kortum (2002) structure. However, with more than two countries, the prices that would prevail in the United States absent China are determined by technology of both the United States and all of its trading partners. Thus, with more than two countries welfare in any individual country is generically not minimized when its relative technology is the same as in China. In fact, it is very easy to construct examples in which the welfare of a particular country actually increases as it becomes more similar to China.

These analytical results underscore the need for a quantitative assessment. Since the welfare outcomes hinge on third country effects and the specifics of productivity distributions of all trading partners, two key inputs are necessary to reach reliable conclusions. The first is a quantitative framework that is global both in country coverage and in the nature of equilibrium adjustments. The second is a comprehensive set of sectoral productivity estimates for a large set of countries. Our analysis employs the productivity estimates recently developed by Levchenko and Zhang (2011) for a sample of 19 manufacturing sectors and 75 economies that includes China along with a variety of countries representing all continents and a wide range of income levels and other characteristics. We embed these productivity estimates within a quantitative multi-country, multi-sector model with a number of realistic features, such as multiple factors of production, an explicit non-traded sector, the full specification of input-output linkages between the sectors, and both inter- and intra-industry trade, among others.

To evaluate the importance of China’s sectoral pattern of growth for global welfare, we simulate two counterfactual growth scenarios starting from the present day. In the first, China’s productivity growth rate in each sector is identical, and equal to the average productivity growth we estimate for China between the 1990s and the 2000s, which is 14% (i.e. an average of 1.32% per annum). In this “balanced” growth scenario, China’s comparative advantage vis-à-vis the world remains unchanged. In the second scenario China’s comparative disadvantage sectors grow disproportionately faster. Specifically, in the “unbalanced” counterfactual China’s relative productivity differences with respect to the world frontier are eliminated, and China’s productivity in every sector becomes a constant ratio of the world frontier. By design, the average productivity in China is the same in the two counterfactuals. What differs is the relative productivities across sectors.

The results are striking. When evaluated quantitatively the welfare impact of China’s growth on the rest of the world turns out to be the opposite of what had been conjectured by Samuelson (2004). The mean welfare gains (the percentage change in real consumption) from the unbalanced growth in China, 0.42% in our sample of 74 countries, are some 40 times larger than the mean gains in the balanced scenario, which are nearly nil at 0.01%. This pattern holds for every region and broad country group. Importantly, the large majority of countries that become more similar to China in the unbalanced growth scenario – most prominently the U.S. and the rest of the

OECD – still gain much more from unbalanced growth in China compared to balanced growth.¹

The analytical results help us understand why this is the case. What matters is not China’s similarity to any individual country, but its similarity to the world weighted average productivity (although the theoretically correct weights will differ from country to country because of trade costs). Closer inspection reveals that China’s current productivity is relatively high in sectors – such as Wearing Apparel – that are “common,” in the sense that many countries also have high productivity in those sectors. By contrast, China’s comparative disadvantage sectors – such as Office, Accounting, and Computing Machinery – are “scarce,” in the sense that not many other countries are close to the global productivity frontier in those sectors. This regularity is very strong in the data: the correlation between China’s relative productivity in a sector and the average productivity in that sector in the rest of the world is 0.86. Put another way, China’s pattern of sectoral productivity is actually fairly similar to the world average. Thus, while balanced growth in China keeps it similar to the typical country, unbalanced growth actually makes it more different. Consistent with theory, our quantitative results imply that the rest of the world would find it more valuable for China to experience productivity growth in the scarce sectors – by a large margin.

As a related exercise of independent interest, we also compare welfare in the baseline model estimated on the world today to a counterfactual in which China is in autarky. This reveals the global distribution of the gains from trade with China as it stands today. The mean welfare gain from adding China to world trade is 0.13%. Dispersion across countries within each region turns out to be large: in nearly every major region or country group, gains range from positive to negative. Aside from China itself, for which the model implies gains of 3.72% relative to autarky, the economies with the largest positive welfare changes are Malaysia (0.80%), Kazakhstan (0.78%), and Taiwan, POC (0.63%). The OECD countries to gain the most are Australia, New Zealand, and Japan (0.26–0.30%). The mean gain in the OECD is 0.13%, with a welfare change for the U.S. of 0.11%.

An often-voiced concern is that China’s export basket is similar to that of many developing countries and emerging markets, and therefore its integration into global trade will reduce the demand for these countries’ exports and potentially lower their welfare (Devlin, Estevaeordal and Rodríguez-Clare, eds 2005, Gallagher, Moreno-Brid and Porzecanski 2008). Our results indeed show that 9 out of 75 countries experience welfare losses, the largest for Honduras (−0.27%) and El Salvador (−0.21%). We correlate the variation in the gains from China’s trade integration with

¹The results are not driven by the choice to equate China’s relative productivities to the world frontier rather than to a particular country. Section 5.5 reports the results of an alternative counterfactual under which Chinese relative productivity in each sector becomes the same as in the U.S.. The welfare gains to the U.S. itself from this counterfactual are virtually identical to the baseline unbalanced counterfactual in which China becomes similar to the world frontier. This counterfactual delivers virtually the same results for the rest of the world as well.

some simple heuristic indicators, such as the similarity of a country's export pattern to China's export pattern. Countries that have similar export baskets to China do tend to gain less/lose more from China's trade integration. Most obviously, all of the countries that experience absolute losses have large Textile and Apparel sectors.

Our paper is related to recent quantitative welfare assessments of trade integration and technological change in multi-sector models (Caliendo and Parro 2010, Costinot, Donaldson and Komunjer 2011, Shikher 2011). Most closely related is the work of Hsieh and Ossa (2011), who consider the welfare impact of the observed pattern of sector-level growth in China from 1992 to 2007 on 14 major countries and 4 broad world regions, and Levchenko and Zhang (2011), who examine the long-run evolution of sectoral technology between the 1960s and the 2000s in a broad range of countries.

The main contribution of this paper relative to existing literature is to reveal the importance of third-country effects, which were not well understood either theoretically or quantitatively. From a theoretical standpoint, we show that any comparative statics exercise on the impact of parameter changes in one country on another country could be fundamentally misleading if carried out in a two-country setting. Accounting for third country effects can change not just the magnitude, but even the sign of the impact. Our quantitative analysis then shows that these effects are strong enough to overturn an influential conjecture about the global impact of changes in China's comparative advantage. To demonstrate our result as transparently as possible, our counterfactual growth scenarios are prospective and designed as a test of a particular hypothesis, rather than retrospective as in Hsieh and Ossa (2011).² Aside from the novel theoretical results on the third-country effects, this paper differs from Levchenko and Zhang (2011) in its set of substantive questions. Levchenko and Zhang (2011) documents the long-run evolution of comparative advantage and emphasizes how comparative advantage changes in individual countries affected their own welfare. This paper's focus is instead on the impact of changes in one country's comparative advantage on the rest of the world, with a particular emphasis on China.

Our work is also related to the Computable General Equilibrium (CGE) assessments of China's trade integration (e.g., Francois and Wignaraja 2008, Ghosh and Rao 2010, Tokarick 2011). Unlike the traditional CGE approach, our quantitative framework is based on Eaton and Kortum (2002)'s Ricardian model of trade with endogenous specialization both within and across sectors, and the focus of the study is on the role of comparative advantage.³ Our global general equilibrium

²In addition, compared to Hsieh and Ossa (2011) our framework has a number features important for a reliable quantitative assessment, such as 75 individual countries, as well as a production structure that includes multiple factors (labor and capital), the full set of input-output linkages between all sectors, and the non-tradeable sector.

³The Armington-based models underlying the CGE approach and the Eaton-Kortum Ricardian models look similar in many dimensions – for instance, they both imply the gravity relationship in trade and under some conditions the gains from trade in those two types of models are summarized by the same sufficient statistics (Arkolakis, Costinot and Rodríguez-Clare 2012). Thus, for some purposes the CGE and the Ricardian quantitative

approach complements recent micro-level studies of the impact of China on developed (e.g., Autor, Dorn and Hanson 2011, Bloom, Draca and Van Reenen 2011, Bitzer, Görg and Schröder 2012) as well as developing (e.g., Hanson and Robertson 2010) countries.

The rest of the paper is organized as follows. Section 2 derives a set of analytical results using a simplified multi-sector N -country Eaton and Kortum (2002) model of Ricardian trade. Section 3 lays out the quantitative framework and describes the details of the calibration. Section 4 examines the welfare implications of both the trade integration of China, and the hypothetical scenarios for Chinese growth. Section 5 performs a set of robustness checks on the quantitative results. Section 6 concludes.

2 Analytical Results

How will the evolution of relative sectoral technology in a country affect its own welfare and the welfare of its trading partners? The answer, based on a two-country costless trade model such as the one employed by Samuelson (2004), is that both countries' welfare is maximized when they have the same relative sectoral productivity. This influential insight must be modified when we step out of this simple environment and consider more than two countries and costly trade. This section derives analytical results and builds intuition in a simplified version of the quantitative model of the next section.

The objective of these simple analytical examples is not to use a 2-sector, 3-country setting to capture the precise story of China, U.S., and the rest of the world – that is the job of the quantitative exercise. Rather, the analytical examples serve to illustrate two main points. First, the exact same productivity change in country 1 can result in welfare changes of opposite signs in country 2, depending on whether there are 2 or 3 countries. Second, when there are more than 2 countries it is easy to construct examples in which as relative productivity in country 1 becomes *more* similar to country 2, country 2's welfare actually *rises*. These two points help understand the mechanisms behind the striking quantitative results.

We analyze a multi-sector Eaton and Kortum (2002, henceforth EK) model, proceeding in three steps. We first consider a version of the model in which relative factor prices in all countries are fixed, and sectoral productivity affects welfare only through the consumption price level. This simplification makes analytical results possible, and allows us to demonstrate most transparently the role of third countries in how sectoral technological similarity between two trading partners

analyses may be broadly comparable. However, the Armington-based CGE approach is fundamentally ill-equipped to study the main questions in this paper, which are about comparative advantage and technological change. In the Armington CGE framework trade is driven by the taste for foreign goods rather than endogenous specialization, and no country would ever start or stop producing any good in response to a productivity change. Since endogenous specialization is at the heart of the Ricardian effects studied here, there is a strong case for using our modeling framework rather than the CGE approach.

affects welfare.

Second, we move to the fully general equilibrium case in which changes in relative sectoral productivity can also affect countries' relative factor prices. Because even the simplest multi-sector model with more than two countries does not admit an analytical solution, we demonstrate the results using numerical examples. The essential message of the model is equally strong under endogenous factor prices. While with 2 countries, welfare is minimized when relative sectoral productivity is the same in the two countries, with 3 countries that is no longer generically the case.

The first two comparative statics are not strictly speaking identical to Samuelson (2004). The classic treatment of unbalanced productivity growth assumes that productivity in one sector rises, while in the other sector it remains unchanged. Thus, there is net productivity growth on average in the partner country. By contrast, our first two comparative statics exercises consider changes in relative sectoral productivity while keeping the average productivity across sectors constant. This approach allows for the cleanest statement of the main results, especially under fixed factor prices, and corresponds precisely to the comparison between our two quantitative counterfactuals, in which we also constrain average productivity to be the same. The third and final step of this section presents the numerical results for the classic experiment, in which one sector's productivity grows while the other sector's productivity remains constant, resulting in net average productivity growth in China. The essential result that adding a third country can reverse the sign of the welfare changes from the same productivity growth is equally true in this experiment.

2.1 The Environment

There are N countries, indexed by n and i . For concreteness, we can think of country 1 as China, and evaluate the impact of technological changes in country 1 on itself and country 2, which we can think of as the United States. There are multiple sectors, indexed by j . Production in each sector follows the EK structure. Output Q_n^j of sector j in country n is a CES aggregate of a continuum of varieties $q = [0, 1]$ unique to each sector:

$$Q_n^j = \left[\int_0^1 Q_n^j(q)^{\frac{\varepsilon-1}{\varepsilon}} dq \right]^{\frac{\varepsilon}{\varepsilon-1}}, \quad (1)$$

where ε denotes the elasticity of substitution across varieties q , and $Q_n^j(q)$ is the amount of variety q that is used in production in sector j and country n .

Producing one unit of good q in sector j in country i requires $\frac{1}{z_i^j(q)}$ units of labor. Productivity $z_i^j(q)$ for each $q \in [0, 1]$ in each country i and sector j is random, drawn from the Fréchet

distribution with cumulative distribution function

$$F_i^j(z) = e^{-T_i^j z^{-\theta}}. \quad (2)$$

In this distribution, the absolute advantage term T_i^j varies by both country and sector, with higher values of T_i^j implying higher average productivity draws in sector j in country i . The parameter θ captures dispersion, with larger values of θ implying smaller dispersion in draws.

Labor is the only factor of production, with country endowments given by L_n and wages denoted by w_n . The production cost of one unit of good q in sector j and country i is thus equal to $w_i/z_i^j(q)$. Each country can produce each good in each sector, and international trade is subject to iceberg costs: $d_{ni}^j > 1$ units of good q produced in sector j in country i must be shipped to country n in order for one unit to be available for consumption there. The trade costs need not be symmetric – d_{ni}^j need not equal d_{in}^j – and will vary by sector. We normalize $d_{nn}^j = 1 \forall n$ and j .

All the product and factor markets are perfectly competitive, and thus the price at which country i can supply tradeable good q in sector j to country n is

$$p_{ni}^j(q) = \left(\frac{w_i}{z_i^j(q)} \right) d_{ni}^j.$$

Buyers of each good q in tradeable sector j in country n will only buy from the cheapest source country, and thus the price actually paid for this good in country n will be

$$p_n^j(q) = \min_{i=1, \dots, N} \left\{ p_{ni}^j(q) \right\}. \quad (3)$$

It is well known that the price of sector j 's output is given by

$$p_n^j = \left[\int_0^1 p_n^j(q)^{1-\varepsilon} dq \right]^{\frac{1}{1-\varepsilon}}.$$

Following the standard EK approach, it is helpful to define

$$\Phi_n^j = \sum_{i=1}^N T_i^j \left(w_i d_{ni}^j \right)^{-\theta}. \quad (4)$$

This value summarizes, for country n , the access to production technologies in sector j . Its value will be higher if in sector j , country n 's trading partners have high productivity (T_i^j) or low cost (w_i). It will also be higher if the trade costs that country n faces in this sector are low. Standard steps (Eaton and Kortum 2002) lead to the familiar result that the price of good j in country n

is simply

$$p_n^j = \Gamma (\Phi_n^j)^{-\frac{1}{\theta}}, \quad (5)$$

where $\Gamma = [\Gamma (\frac{\theta+1-\varepsilon}{\theta})]^{\frac{1}{1-\varepsilon}}$, with Γ the Gamma function.

Consumer utility is identical across countries and Cobb-Douglas with sector j receiving expenditure share η_j . The consumption price level in country n is then proportional to

$$P_n \propto \prod_j (p_n^j)^{\eta_j}, \quad (6)$$

and welfare (indirect utility) is given by the real income w_n/P_n .

2.2 Fixed Relative Wages

Consider first the case in which relative wages are fixed. In particular, suppose there are three sectors, $j = A, B, H$. Sectors A and B have the EK structure described above. As in Helpman, Melitz and Yeaple (2004) and Chaney (2008), good H is homogeneous and can be costlessly traded between any two countries in the world. Let the price of H be the numeraire. In country n , one worker can produce w_n units of H , implying that the wage in n is given by w_n . To obtain the cleanest results, let A and B enter symmetrically in the utility function:

$$U_n = \left(A_n^{\frac{1}{2}} B_n^{\frac{1}{2}} \right)^{\alpha} H_n^{1-\alpha}. \quad (7)$$

Throughout, we assume that α is sufficiently small so that some amount of H is always produced in all the countries in the world. This assumption pins down wages in all the countries, making analytical results possible.

We are now ready to perform the main comparative static: the welfare impact of changes in the relative technology in country 1, T_1^A/T_1^B , subject to the constraint that its geometric average stays the same: $(T_1^A T_1^B)^{\frac{1}{2}} = c$ for some constant c . The exercise informs us of the welfare impact of the different growth scenarios in China, when we hold its average growth rate fixed.

Lemma 1. *Country 1's relative technology $(T_1^A/T_1^B)_n$ that minimizes welfare in country n subject to the constraint $(T_1^A T_1^B)_n^{\frac{1}{2}} = c$ is given by*

$$\left(\frac{T_1^A}{T_1^B} \right)_n = \frac{\sum_{i=2}^N T_i^A \left(\frac{w_i d_{ni}^A}{w_1 d_{n1}^A} \right)^{-\theta}}{\sum_{i=2}^N T_i^B \left(\frac{w_i d_{ni}^B}{w_1 d_{n1}^B} \right)^{-\theta}}. \quad (8)$$

Proof. See Appendix A. □

Lemma 1 says that the country 1 relative technology that minimizes welfare in country n is *not the one* that makes country 1 most similar to country n . That is, generically country n 's welfare is not minimized when $T_1^A/T_1^B = T_n^A/T_n^B$. What matters instead is the relative-unit-cost-weighted average technologies *of all the other countries serving n (including itself)*. Third countries matter through their technology, but also through their relative unit costs and trade costs of serving market n . Because of third country effects, it is easy to construct examples in which country 1 becomes more technologically similar to country n , and yet country n 's welfare increases. Two simple examples under frictionless trade can illustrate the point most clearly.

Example 1. *Suppose there are two countries and trade is costless. Then the country 1 relative technology T_1^A/T_1^B that minimizes welfare in countries 1 and 2 is*

$$\left(\frac{T_1^A}{T_1^B}\right)_1 = \left(\frac{T_1^A}{T_1^B}\right)_2 = \frac{T_2^A}{T_2^B}.$$

Example 2. *Suppose there are three countries and trade is costless. Then the country 1 relative technology T_1^A/T_1^B that minimizes welfare in the three countries is*

$$\left(\frac{T_1^A}{T_1^B}\right)_1 = \left(\frac{T_1^A}{T_1^B}\right)_2 = \left(\frac{T_1^A}{T_1^B}\right)_3 = \frac{T_2^A w_2^{-\theta} + T_3^A w_3^{-\theta}}{T_2^B w_2^{-\theta} + T_3^B w_3^{-\theta}}. \quad (9)$$

In the simple 2-country example the familiar Samuelson (2004) result obtains: both countries are worst off when $T_1^A/T_1^B = T_2^A/T_2^B$. The third country effect is immediate in expression (9). From the perspective of an individual country, it is generically not the case that in any country, welfare is minimized when it is most similar to country 1. In the absence of unit production cost differences ($w_2 = w_3$), welfare is lowest when country 1 is most similar to the simple average productivity of countries other than country 1. When unit costs differ, what matters for welfare is the production-cost-weighted average, and the lower-wage countries will receive a higher weight in this productivity average. Furthermore, as revealed by equation (8), in the presence of trade costs the welfare-minimizing relative productivity is no longer the same for each country as is the case under frictionless trade.

By comparing the three-country expression in (9) to the N -country case in (8), it is also clear that as the number of countries increases, the bilateral technological similarity starts to matter less and less, as the weight of the country itself in the summation decreases. As the number of countries goes up, for country n 's welfare it becomes more and more important how country 1 compares to the countries other than country n rather than to country n itself.

2.3 Endogenous Wages

The preceding results were derived under the assumption that there is a homogeneous costlessly traded good and thus the relative wages do not change in response to relative technology changes in country 1. The advantage of this approach is that we could obtain the main results analytically even with multiple countries and arbitrary iceberg trade costs, and demonstrate most clearly the roles of the various simplifying assumptions. The disadvantage is that general equilibrium movements in relative wages could potentially have independent effects on welfare. Note that as the number of countries increases, the general equilibrium changes in relative wages in response to technical change in an individual country are likely to become smaller and smaller. Nonetheless, it is important to examine whether allowing wages to adjust in the global trade equilibrium weakens any of the analytical results above.

This subsection implements a 2-sector model in which wages adjust in the global trade equilibrium. To that end, we remove the homogeneous good from the model: $\alpha = 1$. To simplify the model further, we assume there are no trade costs ($d_{ni}^j = 1 \forall j, n, i$). Unfortunately, even in the simplest cases, there is no closed-form solution for wages with more than two countries. We first prove analytically that with 2 countries, the welfare-minimizing relative productivity has the same form as in Lemma 1 under these parameter values but now with endogenous wages.

Lemma 2. *Let there be 2 countries and 2 tradeable sectors, with utility given by (7) with $\alpha = 1$. Let there be no international trade costs: $d_{ni}^j = 1 \forall j, n, i$. Assume $T_2^A = T_2^B = 1$ and $L_1 = L_2 = 1$. The country 1 relative technology T_1^A/T_1^B that minimizes welfare in both countries subject to the constraint that $(T_1^A T_1^B)^{\frac{1}{2}} = c$ is given by*

$$\frac{T_1^A}{T_1^B} = \frac{T_2^A}{T_2^B}.$$

Proof. See Appendix A. □

In other words, in this special case the result that perfect similarity minimizes welfare generalizes to a setting with endogenously determined wages. The key to this outcome is in the assumptions that the average productivity in both countries is constant as we vary T_1^A/T_1^B , the two countries have the same size, and trade is costless. As a result, the relative wages remain constant as the relative sectoral productivity in country 1 changes.

However, we cannot provide a corresponding analytical result with three countries. Thus, we compare the outcomes under two and three countries using the following numerical example. Country 2's productivity is the same in the two sectors: $T_2^A = T_2^B = 0.5$. Exactly as above, we vary country 1's relative productivity subject to the constraint that its geometric average equals

0.5 (the same as in country 2). We solve for wages and welfare in all countries numerically for each set of country 1's relative productivities.

In the two-country case the welfare of both countries as a function of T_1^A/T_1^B is plotted in Figure 2(a). As proven analytically, both countries' welfare is at its lowest point when $T_1^A/T_1^B = T_2^A/T_2^B = 1$. Indeed, only one line is distinguishable in the picture: the welfare of the two countries is always the same. Next, we introduce a third country of the same size but with a comparative advantage in sector B : $T_3^A = 0.25$ and $T_3^B = 1$ (so that the geometric average productivity in country 3 is the same as in 1 and 2). Figure 2(b) reports the results. Now, no country's welfare is minimized when T_1^A/T_1^B is the same as its relative technology. Notice that if we start from the right and approach 1 – the point at which $T_1^A/T_1^B = T_2^A/T_2^B$ – welfare of country 2 actually increases slightly. On the other hand, as we approach 1 from the left, the welfare of country 1 rises. All in all, it is clear that country 1 becoming more similar to country 2 no longer implies that either country's welfare falls.

Because the analytical solutions are not available under endogenous wages, we further dissect the mechanisms behind these welfare results by considering two particular values of country 1's technology parameters, and discussing the behavior of price levels and relative wages. The top panel of Table 1 presents the changes in welfare, price levels, and relative wages when moving from $T_1^A/T_1^B = 2$ to $T_1^A/T_1^B = 1$.⁴ Since $T_2^A/T_2^B = 1$, with this technological change country 1 becomes more similar (indeed identical) to country 2. The left column presents the welfare change in the 2-country world. As already shown, greater similarity between the two countries lowers welfare in both. This effect operates entirely through a rise in the consumption price level: the relative wage between the countries does not move. The right column instead presents the results in the 3-country world. The exact same change in technology in country 1 now raises welfare in country 2. Part of what is happening is that due to this change in productivity, w_3/w_2 falls. Thus it appears that in this numerical example, changes in comparative advantage of country 1 lead to a “multilateral relative wage effect:” country 2 gains in welfare over this range partly because technology changes in country 1 lead to cheaper imports from country 3.

Table 1 also reports the changes in sector A net exports as a share of GDP in all the countries (by balanced trade, net exports of sector A and B sum to zero in each country). A greater absolute deviation from zero implies a greater degree of inter-industry trade. With 2 countries, as country 1 becomes more similar to country 2 in relative technology, inter-industry trade disappears entirely: country 2 goes from being a net importer in sector A to balanced trade within the sector. With 3 countries, the same exact change in country 1's technology leads to an *increase* in inter-industry trade in country 2 (a rise in sector A net exports to GDP from 0.05 to 0.11). Thus, just as greater

⁴Welfare in country n is given by w_n/P , where P is the consumption price level. Only one change in P is reported because in this example trade is costless so the consumption price level is the same everywhere.

similarity between countries 1 and 2 need not lower country 2's welfare when there are more than 2 countries, greater similarity also need not reduce inter-industry trade.

Finally, we circle all the way back to the original Samuelson (2004) comparative static in which productivity grows in country 1's comparative disadvantage sector, but stays constant in its comparative advantage sector, implying net average productivity growth in country 1 as it becomes more similar to country 2. In this experiment, $T_1^A = 0.5$ throughout, while T_1^B rises from 0.1 to 0.5. Thus, by design, the end point of this technological change is exactly the same as in the experiment above: countries 1 and 2 end up identical. The bottom panel of Table 1 reports the results. With two countries, it is still the case that as country 1 becomes more similar, country 2 sees absolute welfare losses. Here, the mechanics for the effect are somewhat distinct. While the consumption price level expressed relative to the numeraire – the wage of country 1 – falls, country 2's relative wage falls by more, precipitating welfare losses. By contrast, with three countries, the same change in country 1's technology leads to welfare gains for country 2. Again, part of what is happening is that w_3/w_2 falls, leading to cheaper imports from country 3. Inter-industry trade in country 2 also rises in this experiment.

We conclude from both the analytical results with fixed wages, and the numerical examples with endogenous wages, that third country effects are of first-order importance for evaluating the impact of changes in relative technology in one country on itself and its trading partners. Before moving on to the quantitative analysis, it is worth mentioning the relationship between our results and a common interpretation that the mechanism in the Samuelson (2004)-type result operates through the terms of trade. In the 2×2 first-generation Ricardian model, terms of trade are isomorphic to welfare. The easiest way to see this is to suppose that utility is Cobb-Douglas in two symmetric sectors A and B , country 1 produces A with productivity z_{1A} , while country 2 produces B with productivity z_{2B} . Then, welfare – indirect utility – in country 2 is given by $w_2/P_2 = w_2/(w_2 z_{2B} w_1 z_{1A})^{1/2} = (w_2/w_1)^{1/2} (z_{2B} z_{1A})^{-1/2}$. The terms of trade, on the other hand, are equal to $(w_2/w_1)(z_{2B}/z_{1A})$. Thus, as long as z_{2B} and z_{1A} are unchanged – as was the case in the comparative static considered by Samuelson (2004) – the terms of trade are the same as welfare up to a constant. This equivalence may be helpful to build intuition but it breaks down in more sophisticated models such as EK, where it is no longer the case that the terms of trade are isomorphic to welfare. The conceptually correct object of analysis is indirect utility rather than the terms of trade.

3 Quantitative Framework

To evaluate quantitatively the global welfare impact of balanced and unbalanced sectoral productivity growth in China, we build on the conceptual framework and results above in two respects.

First, we enrich the model in a number of dimensions to make it suitable for quantitative analysis. Relative to the simple model in Section 2, the complete quantitative framework features (i) multiple factors of production – capital and labor; (ii) an explicit nontradeable sector; (iii) input-output linkages between all sectors; (iv) CES aggregation of tradeable consumption goods, with taste differences across goods. Second, we require sectoral productivity estimates (T_n^j) for a large number of countries and sectors in the world. Sectoral productivities are obtained from Levchenko and Zhang (2011), which extends the approach of Eaton and Kortum (2002) and uses bilateral trade data at sector level combined with a model-implied gravity relationship to estimate sector-level productivities. The quantitative framework is implemented on a sample of 75 countries, which in addition to China includes countries from all continents and major world regions.

3.1 The Environment

There are $n, i = 1, \dots, N$ countries, J tradeable sectors, and one nontradeable sector $J + 1$. Utility over the sectors in country n is given by

$$U_n = \left(\sum_{j=1}^J \omega_j^{\frac{1}{\eta}} (Y_n^j)^{\frac{\eta-1}{\eta}} \right)^{\frac{\eta}{\eta-1} \xi_n} (Y_n^{J+1})^{1-\xi_n}, \quad (10)$$

where ξ_n denotes the Cobb-Douglas weight for the tradeable sector composite good, η is the elasticity of substitution between the tradeable sectors, Y_n^{J+1} is final consumption of the nontradeable-sector composite good, and Y_n^j is the final consumption of the composite good in tradeable sector j . Importantly, while Section 2 relied on Cobb-Douglas preferences and symmetry of the tradeable sectors in the utility function, the quantitative model adopts CES preferences and allows ω_j – the taste parameter for tradeable sector j – to differ across sectors.

As in Section 2, output in sector j aggregates a continuum of varieties $q \in [0, 1]$ according to equation (1), and the unit input requirement $\frac{1}{z_i^j(q)}$ for variety q is drawn from the country- and sector-specific productivity distribution given by equation (2). Production uses labor, capital, and intermediate inputs from other sectors. The cost of an input bundle in country i is

$$c_i^j = \left(w_i^{\alpha_j} r_i^{1-\alpha_j} \right)^{\beta_j} \left(\prod_{k=1}^{J+1} (p_i^k)^{\gamma_{k,j}} \right)^{1-\beta_j},$$

where w_i is the wage, r_i is the return to capital, and p_i^k is the price of intermediate input from sector k . The value-added based labor intensity is given by α_j , and the share of value added in total output by β_j . Both vary by sector. The shares of inputs from other sectors $\gamma_{k,j}$ vary by output industry j as well as input industry k . The production cost of one unit of good q in sector j and country n is thus equal to $c_i^j / z_i^j(q)$, and the price at which country i can serve market n is

$p_{ni}^j(q) = \left(\frac{c_i^j}{z_i^j(q)} \right) d_{ni}^j$. The price $p_n^j(q)$ that country n actually pays for good q is given by equation (3).

3.2 Characterization of Equilibrium

The **competitive equilibrium** of this model world economy consists of a set of prices, allocation rules, and trade shares such that (i) given the prices, all firms' inputs satisfy the first-order conditions, and their output is given by the production function; (ii) given the prices, the consumers' demand satisfies the first-order conditions; (iii) the prices ensure the market clearing conditions for labor, capital, tradeable goods and nontradeable goods; (iv) trade shares ensure balanced trade for each country.⁵

The set of prices includes the wage rate w_n , the rental rate r_n , the sectoral prices $\{p_n^j\}_{j=1}^{J+1}$, and the aggregate price P_n in each country n . The allocation rules include the capital and labor allocation across sectors $\{K_n^j, L_n^j\}_{j=1}^{J+1}$, final consumption demand $\{Y_n^j\}_{j=1}^{J+1}$, and total demand $\{Q_n^j\}_{j=1}^{J+1}$ (both final and intermediate goods) for each sector. The trade shares include the expenditure share π_{ni}^j in country n on goods coming from country i in sector j .

3.2.1 Demand and Prices

The price of sector j output in country n is given by equations (4) and (5), with the only difference that the expression for Φ_n^j in equation (4) features c_i^j instead of w_i . The consumption price index in country n is then

$$P_n = B_n \left(\sum_{j=1}^J \omega_j (p_n^j)^{1-\eta} \right)^{\frac{1}{1-\eta} \xi_n} (p_n^{J+1})^{1-\xi_n}, \quad (11)$$

where $B_n = \xi_n^{-\xi_n} (1 - \xi_n)^{-(1-\xi_n)}$.

Both capital and labor are mobile across sectors and immobile across countries, and trade is balanced. The budget constraint (or the resource constraint) of the consumer is thus given by

$$\sum_{j=1}^{J+1} p_n^j Y_n^j = w_n L_n + r_n K_n, \quad (12)$$

where K_n and L_n are the endowments of capital and labor in country n .

Given the set of prices $\{w_n, r_n, P_n, \{p_n^j\}_{j=1}^{J+1}\}_{n=1}^N$, we first characterize the optimal allocations from final demand. Consumers maximize utility (10) subject to the budget constraint (12). The

⁵The assumption of balanced trade is not crucial for the results. Section 5.1 implements a model with unbalanced trade following the approach of Dekle, Eaton and Kortum (2007, 2008), and shows that the conclusions are quite similar.

first order conditions associated with this optimization problem imply the following final demand:

$$p_n^j Y_n^j = \xi_n (w_n L_n + r_n K_n) \frac{\omega_j (p_n^j)^{1-\eta}}{\sum_{k=1}^J \omega_k (p_n^k)^{1-\eta}}, \text{ for all } j = \{1, \dots, J\} \quad (13)$$

and

$$p_n^{J+1} Y_n^{J+1} = (1 - \xi_n) (w_n L_n + r_n K_n).$$

3.2.2 Production Allocation and Market Clearing

The EK structure in each sector j delivers the standard result that the probability of importing good q from country i , π_{ni}^j , is equal to the share of total spending on goods coming from country i , X_{ni}^j / X_n^j , and is given by

$$\frac{X_{ni}^j}{X_n^j} = \pi_{ni}^j = \frac{T_i^j (c_i^j d_{ni}^j)^{-\theta}}{\Phi_n^j}.$$

Let Q_n^j denote the total sectoral demand in country n and sector j . Q_n^j is used for both final consumption and intermediate inputs in domestic production of all sectors. That is,

$$p_n^j Q_n^j = p_n^j Y_n^j + \sum_{k=1}^J (1 - \beta_k) \gamma_{j,k} \left(\sum_{i=1}^N \pi_{in}^k p_i^k Q_i^k \right) + (1 - \beta_{J+1}) \gamma_{j,J+1} p_n^{J+1} Q_n^{J+1}.$$

Total expenditure in sector $j = 1, \dots, J + 1$ of country n , $p_n^j Q_n^j$, is the sum of (i) domestic final consumption expenditure $p_n^j Y_n^j$; (ii) expenditure on sector j goods as intermediate inputs in all the traded sectors $\sum_{k=1}^J (1 - \beta_k) \gamma_{j,k} (\sum_{i=1}^N \pi_{in}^k p_i^k Q_i^k)$, and (iii) expenditure on the j 's sector intermediate inputs in the domestic non-traded sector $(1 - \beta_{J+1}) \gamma_{j,J+1} p_n^{J+1} Q_n^{J+1}$. These market clearing conditions summarize the two important features of the world economy captured by our model: complex international production linkages, as much of world trade is in intermediate inputs, and a good crosses borders multiple times before being consumed (Hummels, Ishii and Yi 2001); and two-way input linkages between the tradeable and the nontradeable sectors.

In each tradeable sector j , some goods q are imported from abroad and some goods q are exported to the rest of the world. Country n 's exports in sector j are given by $EX_n^j = \sum_{i=1}^N \mathbb{I}_{i \neq n} \pi_{in}^j p_i^j Q_i^j$, and its imports in sector j are given by $IM_n^j = \sum_{i=1}^N \mathbb{I}_{i \neq n} \pi_{ni}^j p_n^j Q_n^j$, where $\mathbb{I}_{i \neq n}$ is the indicator function. The total exports of country n are then $EX_n = \sum_{j=1}^J EX_n^j$, and total imports are $IM_n = \sum_{j=1}^J IM_n^j$. Trade balance requires that for any country n , $EX_n - IM_n = 0$.

Given the total production revenue in tradeable sector j in country n , $\sum_{i=1}^N \pi_{in}^j p_i^j Q_i^j$, the optimal sectoral factor allocations must satisfy

$$\sum_{i=1}^N \pi_{in}^j p_i^j Q_i^j = \frac{w_n L_n^j}{\alpha_j \beta_j} = \frac{r_n K_n^j}{(1 - \alpha_j) \beta_j}.$$

For the nontradeable sector $J + 1$, the optimal factor allocations in country n are simply given by

$$p_n^{J+1} Q_n^{J+1} = \frac{w_n L_n^{J+1}}{\alpha_{J+1} \beta_{J+1}} = \frac{r_n K_n^{J+1}}{(1 - \alpha_{J+1}) \beta_{J+1}}.$$

Finally, for any n the feasibility conditions for factors are given by

$$\sum_{j=1}^{J+1} L_n^j = L_n \text{ and } \sum_{j=1}^{J+1} K_n^j = K_n.$$

3.3 Welfare

Welfare in this framework corresponds to the indirect utility function. Straightforward steps using the CES functional form can be used to show that the indirect utility in each country n is equal to total income divided by the price level. Since both goods and factor markets are competitive, total income equals the total returns to factors of production. Thus total welfare in a country is given by $(w_n L_n + r_n K_n) / P_n$, where the consumption price level P_n comes from equation (11). Expressed in per-capita terms it becomes

$$\frac{w_n + r_n k_n}{P_n}, \tag{14}$$

where $k_n = K_n / L_n$ is capital per worker. This expression is the metric of welfare in all counterfactual exercises below.

3.4 Calibration

In order to implement the model numerically, we must calibrate the following sets of parameters: (i) moments of the productivity distributions T_n^j and θ ; (ii) trade costs d_{ni}^j ; (iii) production function parameters α_j , β_j , $\gamma_{k,j}$, and ε ; (iv) country factor endowments L_n and K_n ; and (v) preference parameters ξ_n , ω_j , and η . We discuss the calibration of each in turn.

The structure of the model is used to estimate many of its parameters, most importantly the sector-level technology parameters T_n^j for a large set of countries. The first step, most relevant to this study, is to estimate the technology parameters in the tradeable sectors relative to a reference country (the U.S.) using data on sectoral output and bilateral trade. The procedure relies on fitting a structural gravity equation implied by the model, and using the resulting estimates along with data on input costs to back out underlying technology. Intuitively, if controlling for the typical gravity determinants of trade, a country spends relatively more on domestically produced goods in a particular sector, it is revealed to have either a high relative productivity or a low relative unit cost in that sector. The procedure then uses data on factor and intermediate input prices to net out the role of factor costs, yielding an estimate of relative productivity. This step

also produces estimates of bilateral sector-level trade costs d_{ni}^j . The parametric model for iceberg trade costs includes the common geographic variables such as distance and common border, as well as policy variables, such as regional trade agreements and currency unions.

The second step is to estimate the technology parameters in the tradeable sectors for the U.S.. This procedure requires directly measuring TFP at the sectoral level using data on real output and inputs, and then correcting measured TFP for selection due to trade. The taste parameters for all tradeable sectors ω_j are also calibrated in this step. The third step is to calibrate the nontradeable technology for all countries using the first-order condition of the model and the relative prices of nontradeables observed in the data. The detailed procedures for all three steps are described in Levchenko and Zhang (2011) and reproduced in Appendix B.

In the baseline analysis, we assume that the dispersion parameter θ does not vary across sectors and set $\theta = 8.28$, which is the preferred estimate of EK. Section 5.4 checks the robustness of the results to this assumption in two ways. First, one may be concerned about how the results change under lower values of θ . A lower θ implies greater within-sector heterogeneity in the random productivity draws. Thus, trade flows become less sensitive to the costs of the input bundles (c_i^j), and the gains from intra-sectoral trade become larger relative to the gains from inter-sectoral trade. We repeat the analysis under the assumption that $\theta = 4$, a value that has been advocated by Simonovska and Waugh (2010). This value is at or near the bottom of the range that has been used in the literature. The main conclusions are robust to this alternative value of θ . Second, a number of studies have suggested that θ varies across sectors (see, e.g., Imbs and Méjean 2009, Caliendo and Parro 2010, Chen and Novy 2011). We repeat the analysis allowing θ to be sector-specific, with sectoral values of θ sourced from Caliendo and Parro (2010). Our results are robust to this alternative specification of θ .

The production function parameters α_j and β_j are estimated using the UNIDO Industrial Statistics Database, which reports output, value added, employment, and wage bills at the roughly 2-digit ISIC Revision 3 level of disaggregation. To compute α_j for each sector, we calculate the share of the total wage bill in value added, and take a simple median across countries (taking the mean yields essentially the same results). To compute β_j , we take the median of value added divided by total output.

The intermediate input coefficients $\gamma_{k,j}$ are obtained from the Direct Requirements Table for the United States. We use the 1997 Benchmark Detailed Make and Use Tables (covering approximately 500 distinct sectors), as well as a concordance to the ISIC Revision 3 classification to build a Direct Requirements Table at the 2-digit ISIC level. The Direct Requirements Table gives the value of the intermediate input in row k required to produce one dollar of final output in column j . Thus, it is the direct counterpart to the input coefficients $\gamma_{k,j}$. Note that we assume

these to be the same in all countries.⁶ In addition, we use the U.S. I-O matrix to obtain α_{J+1} and β_{J+1} in the nontradeable sector, which cannot be obtained from UNIDO.⁷ The elasticity of substitution between varieties within each tradeable sector, ε , is set to 4 (as is well known, in the EK model this elasticity plays no role, entering only the constant Γ).

The total labor force in each country, L_n , and the total capital stock, K_n , are obtained from the Penn World Tables 6.3. Following the standard approach in the literature (see, e.g. Hall and Jones 1999, Bernanke and Gürkaynak 2001, Caselli 2005), the total labor force is calculated from the data on the total GDP per capita and per worker.⁸ The total capital is calculated using the perpetual inventory method that assumes a depreciation rate of 6%: $K_{n,t} = (1 - 0.06)K_{n,t-1} + I_{n,t}$, where $I_{n,t}$ is total investment in country n in period t . For most countries, investment data start in 1950, and the initial value of K_n is set equal to $I_{n,0}/(\gamma + 0.06)$, where γ is the average growth rate of investment in the first 10 years for which data are available.

The share of expenditure on traded goods, ξ_n in each country is sourced from Yi and Zhang (2010), who compile this information for 36 developed and developing countries. For countries unavailable in the Yi and Zhang data, values of ξ_n are imputed based their level of development. We fit a simple linear relationship between ξ_n and log PPP-adjusted per capita GDP from the Penn World Tables on the countries in the Yi and Zhang (2010) dataset. The fit of this simple bivariate linear relationship is quite good, with an R^2 of 0.55. For the remaining countries, we then set ξ_n to the value predicted by this bivariate regression at their level of income. The taste parameters for tradeable sectors ω_j were estimated by combining the model structure above with data on final consumption expenditure shares in the U.S. sourced from the U.S. Input-Output matrix, as described in Appendix B. The elasticity of substitution between broad sectors within the tradeable bundle, η , is set to 2. Since these are very large product categories, it is sensible that this elasticity would be relatively low. It is higher, however, than the elasticity of substitution between tradeable and nontradeable goods, which is set to 1 by the Cobb-Douglas assumption.

3.5 Summary of the Estimates and Basic Patterns

All of the variables that vary over time are averaged for the period 2000-2007 (the latest available year), which is the time period on which we carry out the analysis. Appendix Table A1 lists the

⁶di Giovanni and Levchenko (2010) provide suggestive evidence that at such a coarse level of aggregation, Input-Output matrices are indeed similar across countries. To check robustness of the results, we collected country-specific I-O matrices from the GTAP database. Productivities computed based on country-specific I-O matrices were very similar to the baseline values. In our sample of countries, the median correlation was 0.98, with all but 3 out of 75 countries having a correlation of 0.93 or above, and the minimum correlation of 0.65.

⁷The U.S. I-O matrix provides an alternative way of computing α_j and β_j . These parameters calculated based on the U.S. I-O table are very similar to those obtained from UNIDO, with the correlation coefficients between them above 0.85 in each case. The U.S. I-O table implies greater variability in α_j 's and β_j 's across sectors than does UNIDO.

⁸Using the variable name conventions in the Penn World Tables, $L_n = 1000 * pop * rgdpch / rgdpwok$.

74 countries (besides China) used in the analysis, separating them into the major country groups and regions. Appendix Table A2 lists the 20 sectors along with the key parameter values for each sector: α_j , β_j , the share of nontradeable inputs in total inputs $\gamma_{J+1,j}$, and the taste parameter ω_j .

Countries differ markedly with respect to their trade relationship with China. The top panel of Table 2 lists the top 10 and bottom 10 countries in terms of the average trade costs (d_{ni}^j) with China, while the bottom panel reports the top 10 and bottom 10 countries in terms of the correlation between the tradeable sector productivities with China. Since average sectoral productivity scales with $(T_n^j)^{1/\theta}$ rather than T_n^j , and since we want to focus on differences in comparative rather than absolute advantage, we compute the correlations on the vectors of $(T_n^j)^{1/\theta}$ demeaned by each country’s geometric average of those sectoral productivities.

Average trade costs vary from 1.6–1.7 for Japan, Korea and the United States, to 3.95 for Trinidad and Tobago and Ethiopia. Not surprisingly, the trade costs implied by our model correlate positively with distance, with the countries in Asia as the ones with lowest trade costs, though not without exception: the U.S., the U.K, and Germany are in the bottom 10. Technological similarity varies a great deal as well, from correlations in excess of 0.9 with India, Turkey, and Indonesia, to correlations below 0.6 with Sri Lanka, Bolivia, and Iceland. It is clear that the regional component is not as prevalent here, with both most similar and most different countries drawn from different parts of the world.

4 Welfare Analysis

This section analyzes the global welfare impact of China’s trade integration and various productivity growth scenarios. We proceed by first solving the model under the baseline values of all the estimated parameters, and present a number of checks on the model fit with respect to observed data. Then, we compute counterfactual welfare under two main sets of experiments. The first assumes that China is in autarky, and is intended to give a measure of the worldwide gains from trade with China. The second instead starts from today’s equilibrium, and evaluates the implications of alternative patterns of China’s productivity growth going forward. The model solution algorithm is described in Levchenko and Zhang (2011).

4.1 Model Fit

Table 3 compares the wages, returns to capital, and the trade shares in the baseline model solution and in the data. The top panel shows that mean and median wages implied by the model are very close to the data. The correlation coefficient between model-implied wages and those in the data is above 0.99. The second panel performs the same comparison for the return to capital.

Since it is difficult to observe the return to capital in the data, we follow the approach adopted in the estimation of T_n^j 's and impute r_n from an aggregate factor market clearing condition: $r_n/w_n = (1 - \alpha)L_n/(\alpha K_n)$, where α is the aggregate share of labor in GDP, assumed to be 2/3. Once again, the average levels of r_n are very similar in the model and the data, and the correlation between the two is in excess of 0.95.

Next, we compare the trade shares implied by the model to those in the data. The third panel of Table 3 reports the spending on domestically produced goods as a share of overall spending, π_{nn}^j . These values reflect the overall trade openness, with lower values implying higher international trade as a share of absorption. Though we under-predict overall trade slightly (model π_{nn}^j 's tend to be higher), the averages are quite similar, and the correlation between the model and data values is 0.91. Finally, the bottom panel compares the international trade flows in the model and the data. The averages are very close, and the correlation between model and data is 0.9.

Figure 3 presents the comparison of trade flows graphically, by depicting the model-implied trade values against the data, along with a 45-degree line. Red/solid dots indicate π_{ni}^j 's that involve China, that is, trade flows in which China is either an exporter or an importer. All in all the fit of the model to trade flows is quite good. China is unexceptional, with Chinese flows clustered together with the rest of the observations.

We conclude from this exercise that our model matches quite closely the relative incomes of countries as well as bilateral and overall trade flows observed in the data. We now use the model to carry out the two counterfactual scenarios. One captures the gains from trade with China as it stands now. The other considers two possible growth patterns for China.

4.2 Gains from Trade with China

Panel A of Table 4 reports the gains from trade with China around the world. To compute these, we compare welfare of each country in the baseline (current levels of trade costs and productivities as we estimate them in the world today) against a counterfactual scenario in which China is in autarky. The table reports the change in welfare for China itself, as well as the summary statistics for each region and country group. China's gains from trade relative to complete autarky are 3.72%. Elsewhere in the world, the gains range from -0.27% to 0.80% , with the mean of 0.13% .⁹ The gains for the rest of the world from China's trade integration are smaller than for China itself because these gains are relative to the counterfactual that preserves all the global trade relationships other than with China.

⁹This is the unweighted mean across the 74 countries. The population-weighted mean is very close at 0.12% . One may also be interested in comparing the gains from trade with China to other commonly calculated magnitudes in these types of models, such as the total gains from trade. Elsewhere (Levchenko and Zhang 2011) we report that the median gain from trade in this type of model among these 75 countries is 4.5% , with the range from 0.5% to 12.2% .

The countries gaining the most tend to be close to China geographically: Malaysia (0.80%), Kazakhstan (0.78%), and Taiwan, POC (0.63%). Of the top 10, 7 are in Asia, and the remaining three are Peru (0.39%), Chile (0.37%), and Australia (0.30%). The OECD countries to gain the most are Australia, New Zealand, and Japan at 0.26%–0.30%. The mean gain in the OECD is 0.13%, and the welfare change for the U.S. is 0.11%. Table 4 also reveals that in nearly every major country group, the welfare changes range from negative to positive. The countries to lose the most from entry of China into world trade are Honduras (−0.27%) and El Salvador (−21%). All in all, 9 out of 75 countries experience negative welfare changes. By and large, countries that lose tend to be producers of Textiles and Apparel: Sri Lanka, Bulgaria, Vietnam, Mauritius, and Portugal are all among the losing countries.

Our multi-country multi-sector model does not admit an analytical expression for the magnitude of the gains from trade with China, as those gains depend on all the parameters characterizing the country and all of its trading partners. Nonetheless, we investigate whether the variation in the gains from trade with China across countries can be explained – in the least-squares sense – by three simple measures of countries’ multilateral trade linkages with China. The first is the correlation between a country’s export shares and China’s export shares. This measure is meant to capture the extent to which China competes with the country in world product markets. A high correlation means that the country has a very similar export basket to China, and thus will compete with it head-to-head. All else equal, we would expect countries with a higher correlation to experience smaller gains from integration of China.

The second measure is the correlation between a country’s export shares and China’s import shares. This indicator is meant to reflect China’s demand for the goods that the country exports. If the correlation is high, this means China imports a lot of the goods that the country exports, and thus all else equal the country’s gains from introducing China into the world economy should be higher. Finally, the last indicator is the correlation between China’s export shares and the country’s import shares. It is meant to measure the extent to which a country values the goods produced by China: a high correlation means that the country imports a lot of the goods that China exports, which should lead to greater gains, *ceteris paribus*.

In our sample of countries, we regress gains from integration of China on these three heuristic indicators, controlling for the (log) average d_{ni}^j between the country and China, and (log) country population.¹⁰ The overall R^2 in this regression is 0.38. All three are significant and have the expected sign. It is important to emphasize that we do not seek any kind of causal interpretation in this exercise. Instead, the goal is only to find some simple and intuitive indicators that can account for some of the cross-country variation in gains. With that caveat, Figure 4 depicts the partial

¹⁰All the results are unchanged if we use total country GDP instead of population as a measure of size, or if we use levels of d_{ni}^j and population or GDP instead of logs.

correlations between the three indicators of interest and the welfare gains from China's integration. The top panel shows that countries with similar export baskets to China tend to gain less. The relationship is highly significant, with a t -statistic of nearly 4. The middle panel illustrates that countries that export goods imported by China tend to benefit more. The relationship is once again highly significant, with a t -statistic of 4. Finally, the bottom panel shows that countries whose import basket is similar to China's export basket tend to gain more. The relationship is less strong than the other two, but still significant at the 5% level. We conclude from this exercise that the gains from trade with China are well explained by some simple heuristic measures of head-to-head competition with China in world markets, Chinese demand for a country's goods, and Chinese supply of the goods that a country imports.

4.3 Balanced and Unbalanced Growth

The preceding counterfactual was with respect to trade costs: it assumed that trade costs faced by China were prohibitive, and thus it was in autarky. The conjecture put forward by Samuelson (2004) is about uneven technical change in China going forward: given the prevailing level of trade costs, global welfare will be affected differently depending on the pattern of sectoral productivity growth in China.

To evaluate Samuelson's conjecture, we simulate two productivity growth scenarios starting from today's values of China's T_n^j 's. Figure 5 depicts these two counterfactuals graphically. The solid dots, labelled by the sector number, represent the actual ratio of productivity to the global frontier in each sector in China in the 2000s. We can see that the comparative advantage sectors are Coke, Refined Petroleum Products, Nuclear Fuel; Wearing Apparel; and Transport Equipment. The productivity of these sectors is about 0.45–0.5 of the world frontier productivity. The sectors at the greatest comparative disadvantage are Printing and Publishing; Office, Accounting, Computing, and Other Machinery; and Medical, Precision, and Optical Instruments. The productivity of these sectors is around 0.25 of the world frontier. The solid line denotes the geometric average of China's productivity as a ratio to the world frontier productivity in the 2000s, which is about 0.34.¹¹

The two counterfactual productivity scenarios are plotted in the figure. In the balanced growth scenario, we assume that in each sector China's distance to the global frontier has grown by the same proportional rate of 14% (or 1.32% per annum), which is the observed growth of average T_n^j 's in China relative to the world frontier over a decade between the 1990s and the 2000s. The balanced counterfactual productivities are depicted by the hollow dots. In the unbalanced growth counterfactual, we assume that China's average productivity grows by the

¹¹Since mean productivity in each sector is equal to $T^{1/\theta}$, the figure reports the distance to the global frontier expressed in terms of $T^{1/\theta}$, rather than T .

same rate, but its comparative advantage relative to world frontier is erased: in each sector, its productivity is a constant fraction of world frontier. That scenario is depicted by the hollow triangles.¹² An attractive feature of this setup is that in the two counterfactuals, the geometric average productivity across sectors in China is the same. The only thing that is different is the comparative advantage.¹³

Panels B and C of Table 4 present the results for the balanced and the unbalanced counterfactuals, respectively. Appendix Table A1 reports the welfare changes for each individual country. The results are striking. The rest of the world gains much more from unbalanced growth in China. The difference is of an order of magnitude or more. While mean and median gains from balanced growth for the OECD are 0.01–0.02%, they are 0.12–0.17% in the unbalanced growth case. For other regions the difference is even larger: 0.23–0.84% at the mean in the unbalanced case, compared to essentially zero in the balanced case.¹⁴ Figure 6(a) presents the contrast between the welfare changes in the two counterfactual scenarios graphically, by plotting the welfare changes in each country in the balanced case on the y-axis against the welfare changes in the unbalanced case on the x-axis, along with a 45-degree line. While there is a great deal of variation in the welfare changes under the unbalanced case, the balanced counterfactual welfare changes are all very close to zero. In the large majority of cases, the observation is well below the 45-degree line: the country gains more in the unbalanced counterfactual.

These results are diametrically opposite to what has been conjectured by Samuelson (2004), who feared that China’s growth in its comparative disadvantage sectors will hurt the rest of the world. We devote the rest of this section to exploring the mechanisms behind this finding. The analytical section derives the multilateral similarity effect in a simple model with exogenously fixed wages. To isolate the channel emphasized by the analytical results, as an intermediate step we compute an alternative change in welfare under the assumption that w and r do not change from their baseline values.¹⁵ Doing so allows us to focus on the changes in the price levels driven purely by changes in technology parameters rather than relative factor prices. Figure 6(b) presents

¹²Between the 1990s and the 2000s, actual productivity growth has been balanced according to our estimates: while there is some dispersion in sectoral growth rates, comparative disadvantage sectors as of the 1990s had not caught up disproportionately faster to the world frontier.

¹³These counterfactuals match unweighted average productivities. Section 5.5 considers an alternative counterfactual scenario in which weighted-average productivities are matched instead, with the weights being shares of value added or employment. The results are virtually indistinguishable from the main results. We keep productivity in the nontradeable sector at the benchmark value in all the counterfactual experiments, since our focus is on the welfare impact of changes in comparative advantage.

¹⁴Once again, while we report the simple means across countries throughout, population-weighted averages turn out to be very similar. In the sample of 74 countries, under the balanced counterfactual both unweighted and population-weighted mean welfare changes are 0.01%. In the unbalanced counterfactual, the unweighted mean welfare change is 0.42%, compared to the population-weighted average of 0.39%.

¹⁵Note that this of course does not involve a solution to the model, and these values do not correspond to any actual equilibrium. They are simply the hypothetical values of the change in the welfare expression (14) that obtain when w_n and r_n remain at their baseline values but T_n^j ’s for China change to their counterfactual values.

a scatterplot of the welfare changes in the balanced counterfactual against the welfare changes in the unbalanced one under fixed factor prices. The essential result that the world gains much more from unbalanced growth in China still obtains when factor prices do not change. The mechanism highlighted in the analytical section clearly contributes to generating the quantitative results.

As demonstrated in Section 2, what matters for an individual country is how China’s technology compares not to itself, but to appropriately averaged world productivity. Figure 7 plots China’s distance to the global frontier in each sector against the simple average of the distance to the global frontier in all the countries in the sample except China, along with the least-squares fit. The world average distance to the frontier captures in a simple way how productive countries are on average in each sector. Higher values imply that the world as a whole is fairly productive in those sectors. Lower values imply that the world is fairly unproductive in those sectors.

The relationship is striking: China’s comparative advantage sectors are also the ones in which other countries tend to be more productive. The simple correlation between these two variables is a remarkable 0.86.¹⁶ Thus, China’s comparative advantage is in “common” sectors, those in which many other countries are already productive, most obviously Wearing Apparel. By contrast, China’s comparative disadvantage is in “scarce” sectors in which not many countries are productive, for example Medical, Precision, and Optical Instruments. Thus, it is more valuable for the world if China improves productivity in the globally scarce sectors.

Having isolated the impact of multilateral similarity by fixing w and r , we next explore the role of endogenous factor prices. Figure 8 plots the welfare change under endogenous w and r on the y-axis against the welfare change under fixed w and r on the x-axis. Panel (a) reports the scatterplot for the balanced counterfactual, while panel (b) for the unbalanced counterfactual. Several things stand out about the role of endogenous factor prices. First, in all countries (of course, except China) and both counterfactuals, the gains are larger under fixed factor prices. This is not surprising: when factor prices are fixed, the technological improvement in China is not accompanied by rising factor costs, giving all the countries except China a benefit of better technology without the cost of higher Chinese wages and returns to capital.

Second, in the balanced counterfactual, from the perspective of almost every country, the benefit from better Chinese technology is essentially perfectly cancelled out by the higher factor prices in China. While there is some dispersion in how much countries gain under fixed factor prices (from zero to 2%), that dispersion disappears when factor prices are allowed to adjust. Countries that gain more from better Chinese technology when w and r are fixed also lose more from higher w and r in China, such that the net gains to them are nil.

Third, the counteracting movements in w and r are weaker in the unbalanced counterfactual.

¹⁶The plot and the reported correlation drop Tobacco, which is a small sector and an outlier. With Tobacco, the correlation is 0.78.

In contrast to the balanced growth case, it is not generally the case that the benefits to countries from Chinese technological change are perfectly undone by movements in factor prices. That off-setting effect exists, but it is much less strong. There is a clear positive relationship between welfare gains under fixed factor prices and gains with flexible ones: countries that gain the most from changes in Chinese technology when factor prices are fixed continue to gain more when factor prices adjust. Thus, there is an additional effect of unbalanced growth that works through endogenous factor prices: compared to balanced growth, Chinese relative factor prices do not rise as much, and thus wipe out less of the gains to other countries from average productivity increases in China.

Next we explore technological similarity as a determinant of the gains from unbalanced growth in China. Figure 9(a) plots the welfare change in the unbalanced counterfactual against the simple change in the correlation of T 's between the country and China. In other words, unbalanced growth in China makes China less technologically similar to the countries below zero on the x-axis, and more similar to the countries above zero on the x-axis. The figure also depicts the OLS fit through the data. The relationship is negative and very significant: in this bivariate regression, the R^2 is 0.3 and the robust t -statistic on the change in technological similarity variable is 5. Countries that become more similar to China as a result of China's unbalanced growth thus tend to gain less from that growth. (Note that as shown in Figure 6(a), nearly all countries, including ones that become more similar to China, nonetheless gain more from unbalanced growth compared to the balanced one.)

There could be two explanations for this robust negative correlation. The first is that when China becomes more similar, demand for the country's output goes down, pushing down factor prices. As a result, the country would gain less. The second explanation is about how trade costs affect multilateral similarity. Equation (8) shows that in the presence of trade costs, T_n^A and T_n^B will get a larger weight in the right-hand side expression for country n . That is, when d_{ni}^j 's are substantial, country n 's similarity with China matters more than China's similarity to some other country i . The multilateral similarity effect is still of first-order importance in explaining the difference between the balanced and unbalanced growth outcomes. But when examining the variation in welfare gains across countries under the unbalanced counterfactual, the changes in bilateral technological similarity with China become relevant. To isolate the second effect, Figure 9(b) relates changes in technological similarity to welfare changes in the unbalanced counterfactual but this time under fixed factor prices. The strength of the negative relationship is the same: both the R^2 and the t -statistic on the coefficient are virtually identical to the plot with endogenous wages. We conclude that the negative relationship in Figure 9(a) is not due purely to movements in factor prices.

Finally, China itself gains slightly more from a balanced growth scenario than from unbal-

anced growth, 11.43% compared to 10.57%, a difference of almost a percentage point. This result is driven by uneven consumption weights across sectors. It turns out that Chinese sectoral productivity today is strongly positively correlated with the sectoral taste parameter ω_j , with a correlation of nearly 0.5. In a world characterized by high trade costs, a country would be better off with higher productivity in sectors with high taste parameters, all else equal. In the unbalanced counterfactual, China's productivity in high-consumption-weight sectors becomes relatively lower.

5 Robustness

This section presents a number of robustness checks on the main results. We describe the results of (i) incorporating trade imbalances; (ii) adding non-manufacturing production and trade; (iii) using directly measured productivities in countries where they are available; (iv) carrying out all of the analysis under an alternative value of the dispersion parameter θ ; and (v) considering alternative specifications of the unbalanced counterfactual.

5.1 Trade Imbalances

One aspect of Chinese trade that has receives a lot of attention is its large surpluses in goods trade. Trade surpluses result from dynamic decisions, whereas our model is static in nature. In the absence of a working model that explains trade imbalances, we incorporate the impact of trade imbalances following the approach of Dekle, Eaton and Kortum (2007, 2008) and assuming that at a point in time, a trade imbalance represents a transfer from the surplus to the deficit country. Specifically, the budget constraint (or the resource constraint) of the consumer is now

$$\sum_{j=1}^{J+1} p_n^j Y_n^j = w_n L_n + r_n K_n - D_n,$$

where D_n is the trade surplus of country n . When D_n is negative, countries are running a deficit and consume more than their factor income. The deficits add up to zero globally, $\sum_n D_n = 0$, and are thus transfers of resources between countries. The rest of the model remains the same. In implementing the model, the deficits are taken directly from the data. To evaluate how trade imbalances affect our quantitative results, we want to ignore the transfer itself. In other words, when the U.S. opens to trade with China, in this model there will be gains from goods trade, but also direct income gains from the transfer of resources from China to the U.S.. In calculating the welfare impact, we abstract from the latter, since in the intertemporal sense, it is not really a transfer. Thus, in the model with deficits, the metric for welfare continues to be equation (14).

In evaluating the welfare gains from trade with China, we assume that when China is in

autarky, its bilateral imports and exports (and thus bilateral deficits) with each country are set to zero. Thus, the rest of the world’s bilateral trade imbalances remain unchanged, and trade is still generically not balanced for the other 74 countries. In the balanced and unbalanced growth counterfactuals, we assume that the vector of D_n ’s in the world remains the same. Both assumptions are not perfect, but without a working model of endogenous determination of D_n ’s, there is no clearly superior alternative.

Table 5 reports the results in a model with trade imbalances. Not surprisingly, China gains about half a percentage point less compared to the model without trade imbalances, since in the trade equilibrium it is transferring resources abroad, while the rest of the world gains more with trade imbalances. Note that we are not counting the direct impact of income transfers in the welfare calculations. Thus, larger gains from trade with China to the rest of the world compared to the baseline model come from the general equilibrium effects on goods and factor prices. Intuitively, a country receiving a transfer will experience an increase in demand, which will push up factor prices, while in the country sending out the transfer (China), factor prices will be lower relative to the model in which trade is balanced. Consequently, countries receiving the transfers gain more from trade with China in the model with trade imbalances (Dornbusch et al. 1977).

The global impact of balanced and unbalanced growth in China is very similar to the baseline results. The mean welfare impact of balanced growth in China, 0.003%, is slightly smaller than without trade deficits, but of the same order of magnitude. The mean gains from unbalanced growth, 0.39%, are very similar to the baseline case. In each growth scenario, the gains across countries with and without trade deficits have a correlation coefficient of above 0.93.

5.2 Agriculture and Mining Sectors

Another concern is that the baseline model includes only manufacturing sectors in the tradeable sector. Exclusion of agricultural and mining production and trade is unlikely to have a large impact on the results, as agriculture and mining account for only about 14% of global trade in the 2000s. To check robustness of the results, we collected data on total output in Agriculture, Hunting, Forestry and Fishing (“Agriculture” for short) and Mining and Quarrying (“Mining”) from the United Nations Statistics Division. The output data are not available at a finer level of disaggregation. Several countries in our sample did not have information on agricultural and mining output in this database. In those cases, we imputed total output in these sectors by using agricultural and mining value added data from the World Bank’s World Development indicators, and “grossing up” value added data by $1/(1 - \beta_j)$ to obtain a guess for total gross output. Though we performed extensive quality and consistency checks on the resulting data points, one

must treat them with caution, as they come from different sources than the manufacturing data, are in several important cases imputed, and are clearly observed at a coarser level of aggregation than manufacturing.

Combining agricultural and mining output data with information on bilateral trade, we estimate T_n^j 's and d_{ni}^j 's in those two sectors in each country using the same procedure as for manufacturing, described in Appendix B. We use the U.S. Input-Output table, which includes information on non-manufacturing, to compute α_j , β_j , and all the $\gamma_{k,j}$'s associated with agriculture and mining as either output or input sectors. We also use the U.S. Input-Output table for the final consumption shares of those sectors, in order to estimate non-manufacturing ω_j 's. We apply the same value of θ to non-manufacturing sectors as we do to the rest of the model. Note that because of input-output linkages between all the sectors, adding non-manufacturing affects all of the productivity estimates, including those of the manufacturing sector. Thus, adding non-manufacturing involves re-running the entire estimation procedure for all sectors from scratch.

Having estimated all the technology and trade cost parameters for non-manufacturing, we then solve the full model augmented with the non-manufacturing sectors, and perform all of the counterfactuals. The results are reported in Table 6. By and large, the conclusions are unchanged. The magnitudes of the gains/losses from trade with China are remarkably similar. Exactly as in the baseline model, the gains from unbalanced growth are an order of magnitude larger than the gains from balanced growth.

5.3 Directly Measured Productivity

One may also be concerned that the results may be unduly influenced by the way sectoral productivity is measured. The productivity estimates used in this analysis rely on extracting information from international trade flows. An alternative approach would be to use sectoral data on output and inputs and measure TFP using the standard Solow residual approach. As detailed in Levchenko and Zhang (2011), the basic difficulty in directly measuring sectoral TFP in a large sample of countries and over time is the lack of comparable data on real sectoral output and inputs. To our knowledge, the most comprehensive database that can be used to measure sectoral TFP on a consistent basis across countries and time is the OECD Structural Analysis (STAN) database. It contains the required information on only 11 developed countries: Austria, Belgium, Czech Republic, Denmark, Finland, France, Greece, Italy, Norway, Slovenia, and Sweden (though upon closer inspection it turns out that the time and sectoral coverage is poor even in that small set of countries). Nonetheless, to check robustness of our results, we built direct TFP estimates for those 11 countries, and used them instead of the international trade-implied baseline estimates.

The resulting welfare changes are quite similar to the baseline results: for all three counterfac-

tuals, the correlation between the welfare changes in the main analysis and the welfare changes using STAN-based estimates is above 0.99. The magnitudes of the welfare changes are very similar to the main results as well. Table 7 replicates all of the welfare results using the STAN-based productivity estimates for the available countries. The average welfare impacts in all three panels are very similar, and the contrast between the balanced and the unbalanced growth counterfactuals is equally stark. We conclude from this exercise that using direct estimates of productivity wherever those are available does not change the main message of the analysis.

5.4 Alternative Assumptions on the Dispersion Parameter θ

As mentioned in the calibration section, one may be concerned about the sensitivity of the results with respect to the choice of the parameter θ . We check the robustness of the results under (i) a lower value of θ and (ii) sector-specific values of θ .

In the EK model, θ measures dispersion of productivity draws. Our baseline analysis uses the EK preferred value of 8.28, which is relatively high compared to others used in the literature, implying a relatively low dispersion in productivity draws within sectors. We thus repeat the analysis under an alternative, lower value of $\theta = 4$. This value is at or near the bottom of the range suggested in the literature, and has been advocated by Simonovska and Waugh (2010). Note that adopting an alternative value of θ requires re-estimating the model, most importantly all of the T_n^j 's and d_{ni}^j 's. While all of the parameters in principle change, in practice the correlation between estimated T_i^j 's under $\theta = 4$ and the baseline is above 0.95, and there is actually somewhat greater variability in T_i^j 's under $\theta = 4$.

The results of the analysis under $\theta = 4$ are presented in Table 8. None of the substantive results are affected by the choice of θ . Most importantly, the world gains far more in the unbalanced counterfactual (0.52%) compared to the balanced one (0.03%). As the table makes clear, this pattern is evident in every region, and is equally pronounced as in the baseline. As expected, the absolute numbers are different, generally implying larger gains from trade with China. For China itself, the gains relative to autarky are 6.22% instead of 3.72% in the baseline, while for the rest of the world the gain from trade with China are 0.28% compared to the baseline 0.13%.

Recent contributions have argued that θ actually varies across sectors (Imbs and Méjean 2009, Caliendo and Parro 2010, Chen and Novy 2011). To check whether our results are affected by the assumption that θ is the same across sectors, we re-implement the model with sector-specific θ_j 's. Since Caliendo and Parro (2010)'s framework is closest to ours, we adopt the θ_j estimates in that paper. Once again, this robustness check requires re-estimating the entire set of T_n^j 's and d_{ni}^j 's under sector-specific θ_j 's. The results are presented in Table 9. Our main results are robust to incorporating sector-specific θ_j 's into the exercise. The world gains far more from the unbalanced

growth in China compared to balanced growth.

5.5 Alternative Unbalanced Counterfactuals

Finally, we assess to what extent the quantitative results are driven by the particular form of the unbalanced counterfactual we impose. One concern is that to make the Chinese sectoral productivity a constant fraction of the world frontier in every sector while at the same time keeping the average productivity the same as in the balanced counterfactual, some sectors must actually experience an absolute reduction in productivity relative to the baseline. Thus, it is important to check that our main results are not driven by absolute productivity reductions. To that end, we implement two alternative unbalanced counterfactuals. The first, which we call “linear,” keeps the productivity of the top sector constant, and “rotates up” the relative productivities of the other sectors around the top sector. That is, the productivity of the second-most productive sector is set equal to the productivity of the top sector times a constant $\delta < 1$. The productivity of the third-most productive sector is then the productivity of the top sector times δ^2 and so on. This is done subject to the constraint that the resulting average counterfactual productivity is the same as in the main balanced and unbalanced counterfactuals.

The second alternative unbalanced counterfactual, called “no regress,” imposes productivity that is a constant fraction of the world frontier in every sector, unless doing so would imply an absolute productivity reduction in a sector, in which case productivity in the sector is kept constant. Once again, counterfactual productivities in this scenario are set such that the resulting average productivity is the same as in all the other balanced and unbalanced counterfactuals. Importantly, in both of these alternative counterfactuals no sector experiences an absolute productivity reduction.

The next counterfactual we implement is one in which Chinese productivity relative to the world frontier in each sector is the same as the U.S. productivity relative to the world frontier, up to a multiplicative constant, once again subject to the constraint that average Chinese productivity is the same as in all the other counterfactuals. This counterfactual does imply technological regress in some sectors relative to the baseline. However, it allows us to check whether there is something special about productivity in China becoming the same as the world frontier, as opposed to another individual country. The sectoral productivities under these three alternative counterfactuals are depicted graphically in Appendix Figure A1.

Finally, all of the previous counterfactual scenarios have been set up so that the unweighted (geometric) average growth rate of T_n^j is the same between the balanced and the unbalanced counterfactuals – or, equivalently, the geometric average levels of counterfactual productivities are the same. However, if sectors in China are of different initial size, it could be that the weighted-average

growth rate – i.e., measured aggregate productivity growth – is different between unbalanced and balanced growth scenarios. Thus, we implement an alternative unbalanced counterfactual, that instead matches the sector size-weighted growth rate of productivity to the balanced counterfactual growth rate, where sector size is proxied by its share in total tradeable value added.¹⁷ The difference in the unbalanced productivity level between the unweighted and the weighted case is small: while in the unweighted case, each sector’s productivity is about 0.39 of the world frontier, in the weighted case it is slightly higher at 0.41.

The counterfactual welfare results are summarized in Appendix Table A3. The top panel presents the summary statistics for the welfare impact under each counterfactual on all the countries other than China. For ease of comparison, the top two rows present the two main counterfactuals in the paper, the balanced and the unbalanced. The last four rows describe the alternative unbalanced counterfactuals. All four alternative unbalanced counterfactuals produce average welfare impacts that are an order of magnitude greater than the balanced case. The smallest impact, produced by the “linear” counterfactual, is still 10 times larger on average compared to the balanced counterfactual. The fact that the “linear” counterfactual implies smaller welfare changes is not surprising, since it is by far the closest to the balanced case. Matching size-weighted rather than unweighted productivity growth produces a slightly larger welfare impact on the rest of the world.

The bottom panel of Appendix Table A3 presents the correlations between the welfare impacts of all six counterfactuals we consider. What is remarkable is that while the welfare impact of the balanced counterfactual is virtually uncorrelated with any of the unbalanced counterfactuals, all of the unbalanced counterfactuals are extremely highly correlated amongst themselves, with correlation coefficients ranging from 0.94 to virtually 1. The size-weighted counterfactual in particular produces virtually indistinguishable outcomes compared to the unweighted one. We conclude from this exercise that the essential contrast between the balanced and the unbalanced cases is robust to alternative ways of defining the unbalanced counterfactual. In all cases, the world benefits much more from unbalanced growth in China.

The counterfactual in which we set Chinese relative productivity to the U.S. values can be used to check how welfare in the U.S. changes when China becomes *exactly* like the U.S. in relative productivity. It turns out that the gains to the U.S. from China becoming exactly like it, 0.174%, are nearly the same as the 0.178% U.S. gains in the main unbalanced counterfactual. The U.S. turns out to gain about the same from China becoming exactly like itself as from China becoming the same as the world frontier, and much more than it gains in the balanced counterfactual.

¹⁷The results are identical if we use employment-weighted averages instead. Of course, since in the balanced counterfactual every sector has the same growth rate, it doesn’t matter how they are weighted. Thus, this alternative counterfactual only affects the numbers for the unbalanced counterfactual.

6 Conclusion

The sheer size of the Chinese economy and the breathtaking speed of its integration into global trade have led to concerns about the possible negative welfare effects of China's integration and productivity growth. These concerns correspond to the theoretically possible – though not necessary – outcomes in fully articulated models of international trade, and thus have been taken seriously by economists. However, it is ultimately a quantitative question whether the negative welfare effects of China on its trading partners actually obtain in a calibrated model of the world economy with a realistic production structure, trade costs, and the inherently multilateral nature of international trade.

This paper investigates the global welfare impact of China's trade integration and productivity growth in a multi-country, multi-sector Ricardian-Heckscher-Ohlin model of production and trade. With respect to China's trade integration, our main finding is that the gains range from negative to positive, with Asian countries on average gaining more, while many countries in which Textile and Apparel sectors are important actually experiencing small welfare losses. With respect to technological change, our results are more surprising: contrary to a well-known conjecture, the world will actually gain much more in welfare if China's growth is unbalanced. This is because China's current pattern of comparative advantage is common in the world, and thus unbalanced growth in China actually makes it more different than the average country. Both analytical and quantitative results point to the crucial importance of taking explicit account of the multilateral nature of both Ricardian comparative advantage and trade flows in evaluating the global welfare impact of China.

Appendix A Proofs for Lemmas in Section 2

Proof of Lemma 1: Combining equations (5) and (6), welfare can be expressed as:

$$\begin{aligned} w_n/P_n &= w_n (p_n^A p_n^B)^{-\frac{1}{2}\alpha} (p_n^H)^{\alpha-1} \\ &\propto \left\{ \left[\sum_{i=1}^N T_i^A (w_i d_{ni}^A)^{-\theta} \right] \left[\sum_{i=1}^N T_i^B (w_i d_{ni}^B)^{-\theta} \right] \right\}^{\frac{\alpha}{2\theta}}, \end{aligned} \quad (\text{A.1})$$

From (A.1) and the constraint that $(T_1^A T_1^B)^{\frac{1}{2}} = c$, welfare in country n as a function of T_1^A becomes

$$\left\{ \left[T_1^A + \sum_{i=2}^N T_i^A \left(\frac{w_i d_{ni}^A}{w_1 d_{n1}^A} \right)^{-\theta} \right] \left[\frac{1}{T_1^A} + \frac{1}{c^2} \sum_{i=2}^N T_i^B \left(\frac{w_i d_{ni}^B}{w_1 d_{n1}^B} \right)^{-\theta} \right] \right\}^{\frac{\alpha}{2\theta}}.$$

Taking the first-order condition with respect to T_1^A yields the following welfare-minimizing value:

$$T_1^A = c \sqrt{\frac{\sum_{i=2}^N T_i^A \left(\frac{w_i d_{ni}^A}{w_1 d_{n1}^A} \right)^{-\theta}}{\sum_{i=2}^N T_i^B \left(\frac{w_i d_{ni}^B}{w_1 d_{n1}^B} \right)^{-\theta}}}.$$

The second-order condition easily verifies that this is indeed a (global) minimum. Using the welfare-minimizing T_1^A together with $(T_1^A T_1^B)^{\frac{1}{2}} = c$ leads to the expression for relative technologies (8). Q.E.D.

Proof of Lemma 2: Since trade is costless, the price levels are equalized across countries, at both sectoral and aggregate levels. Thus for $j \in \{A, B\}$

$$P_1^j = P_2^j = P^j = \left[T_1^j w_1^{-\theta} + T_2^j w_2^{-\theta} \right]^{-\frac{1}{\theta}},$$

and the consumption price level in both countries is given by

$$P = \sqrt{P^A P^B}.$$

The welfare of country 1, w_1/P , then becomes

$$W_1^{2\theta} = w_1^{2\theta} \left[w_1^{-\theta} T_1^A + w_2^{-\theta} T_2^A \right] \left[w_1^{-\theta} T_1^B + w_2^{-\theta} T_2^B \right].$$

When we normalize $w_1 = 1$, set $T_2^A = T_2^B = 1$, and constrain $T_1^A T_1^B = 1$ as T_1^A varies,

$$W_1^{2\theta} = \left[T_1^A + w_2^{-\theta} \right] \left[(T_1^A)^{-1} + w_2^{-\theta} \right] = 1 + w_2^{-\theta} \left[T_1^A + (T_1^A)^{-1} \right] + w_2^{-2\theta}.$$

Similarly, welfare in country 2 is

$$W_2^{2\theta} = w_2^{2\theta} + w_2^\theta \left[T_1^A + (T_1^A)^{-1} \right] + 1.$$

Clearly, since the prices are equalized across countries, the ratio of welfares equals the ratio of

wages:

$$\frac{W_2}{W_1} = w_2.$$

If the wages are pinned down by another homogeneous sector, it is clear that the welfare-minimizing T_1^A satisfies $T_1^A/T_1^B = 1$ – the same ratio of productivities as in country 2. Now consider the general equilibrium effect on wages. The derivatives of welfare with respect to T_1^A are equal to

$$\frac{dW_1^{2\theta}}{dT_1^A} = -\theta w_2^{-\theta-1} \left[T_1^A + (T_1^A)^{-1} + 2w_2^{-\theta} \right] \frac{dw_2}{dT_1^A} + w_2^{-\theta} \left[1 - (T_1^A)^{-2} \right]$$

and

$$\frac{dW_2^{2\theta}}{dT_1^A} = \theta w_2^{\theta-1} \left[T_1^A + (T_1^A)^{-1} + 2w_2^\theta \right] \frac{dw_2}{dT_1^A} + w_2^\theta \left[1 - (T_1^A)^{-2} \right].$$

Setting the first order conditions to zero, we have

$$\frac{dw_2}{dT_1^A} = \frac{w_2}{\theta} \frac{1 - (T_1^A)^{-2}}{T_1^A + (T_1^A)^{-1} + 2w_2^{-\theta}},$$

and

$$\frac{dw_2}{dT_1^A} = -\frac{w_2}{\theta} \frac{1 - (T_1^A)^{-2}}{T_1^A + (T_1^A)^{-1} + 2w_2^\theta}.$$

At first glance, the welfare-minimizing points do not appear to be the same for countries 1 and 2. However, we will show next that in equilibrium, $dw_2/dT_1^A = 0$ and $w_2 = 1$ for any T_1^A . Thus the welfare-minimizing relative productivity is the same for both countries and is such that $T_1^A/T_1^B = 1$.

Under frictionless trade, trade shares are given by

$$\pi_{12}^A = \frac{w_2^{-\theta}}{T_1^A + w_2^{-\theta}} = 1 - \pi_{21}^A$$

and

$$\pi_{12}^B = \frac{w_2^{-\theta}}{(T_1^A)^{-1} + w_2^{-\theta}} = 1 - \pi_{21}^B.$$

Therefore, the net exports in each tradable sector $j \in \{A, B\}$ are given by

$$NX_1^j = \pi_{21}^j X_2^j w_2 L_2 - \pi_{12}^j X_1^j w_1 L_1 = \frac{1}{2} \left(\pi_{21}^j w_2 - \pi_{12}^j \right) = \frac{1}{2} \left(\pi_{21}^j (w_2 + 1) - 1 \right),$$

where the symmetric Cobb-Douglas preferences across the two sectors lead to expenditure shares $X_2^s = X_1^s = \frac{1}{2}$ and we used the assumption that $L_1 = L_2 = 1$. The balanced-trade condition then implies

$$w_2 = \frac{\pi_{12}^A + \pi_{12}^B}{\pi_{21}^A + \pi_{21}^B}.$$

Plugging in the expressions for the trade shares in the above equation yields

$$2w_2^{\theta+1} + w_2 \left[T_1^A + (T_1^A)^{-1} \right] - 2w_2^{-\theta} - \left[T_1^A + (T_1^A)^{-1} \right] = 0.$$

Clearly $w_2 = 1$ is the solution to the above trade balance condition for any T_1^A , which also implies $\frac{dw_2}{dT_1^A} = 0$. Q.E.D.

Appendix B Procedure for Estimating T_n^j , d_{ni}^j , and ω_j

This appendix reproduces from Levchenko and Zhang (2011) the details of the procedure for estimating technology, trade costs, and taste parameters required to implement the model. Interested readers should consult that paper for further details on estimation steps and data sources.

B.1 Tradeable Sector Relative Technology

We now focus on the tradeable sectors. Following the standard EK approach, first divide trade shares by their domestic counterpart:

$$\frac{\pi_{ni}^j}{\pi_{nn}^j} = \frac{X_{ni}^j}{X_{nn}^j} = \frac{T_i^j (c_i^j d_{ni}^j)^{-\theta}}{T_n^j (c_n^j)^{-\theta}},$$

which in logs becomes:

$$\ln \left(\frac{X_{ni}^j}{X_{nn}^j} \right) = \ln \left(T_i^j (c_i^j)^{-\theta} \right) - \ln \left(T_n^j (c_n^j)^{-\theta} \right) - \theta \ln d_{ni}^j.$$

Let the (log) iceberg costs be given by the following expression:

$$\ln d_{ni}^j = d_k^j + b_{ni}^j + CU_{ni}^j + RTA_{ni}^j + ex_i^j + \nu_{ni}^j,$$

where d_k^j is an indicator variable for a distance interval. Following EK, we set the distance intervals, in miles, to $[0, 350]$, $[350, 750]$, $[750, 1500]$, $[1500, 3000]$, $[3000, 6000]$, $[6000, \text{maximum}]$. Additional variables are whether the two countries share a common border (b_{ni}^j), belong to a currency union (CU_{ni}^j), or to a regional trade agreement (RTA_{ni}^j). Following the arguments in Waugh (2010), we include an exporter fixed effect ex_i^j . Finally, there is an error term ν_{ni}^j . Note that all the variables have a sector superscript j : we allow all the trade cost proxy variables to affect true iceberg trade costs d_{ni}^j differentially across sectors. There is a range of evidence that trade volumes at sector level vary in their sensitivity to distance or common border (see, among many others, Do and Levchenko 2007, Berthelon and Freund 2008).

This leads to the following final estimating equation:

$$\ln \left(\frac{X_{ni}^j}{X_{nn}^j} \right) = \underbrace{\ln \left(T_i^j (c_i^j)^{-\theta} \right)}_{\text{Exporter Fixed Effect}} - \underbrace{\theta ex_i^j}_{\text{Importer Fixed Effect}} - \ln \left(T_n^j (c_n^j)^{-\theta} \right) \\ \underbrace{-\theta d_k^j - \theta b_{ni}^j - \theta CU_{ni}^j - \theta RTA_{ni}^j}_{\text{Bilateral Observables}} \underbrace{-\theta \nu_{ni}^j}_{\text{Error Term}} .$$

This equation is estimated for each tradeable sector $j = 1, \dots, J$. Estimating this relationship will thus yield, for each country, an estimate of its technology-cum-unit-cost term in each sector j , $T_n^j (c_n^j)^{-\theta}$, which is obtained by exponentiating the importer fixed effect. The available degrees of freedom imply that these estimates are of each country's $T_n^j (c_n^j)^{-\theta}$ relative to a reference country, which in our estimation is the United States. We denote this estimated value by S_n^j :

$$S_n^j = \frac{T_n^j}{T_{us}^j} \left(\frac{c_n^j}{c_{us}^j} \right)^{-\theta} ,$$

where the subscript us denotes the United States. It is immediate from this expression that estimation delivers a convolution of technology parameters T_n^j and cost parameters c_n^j . Both will of course affect trade volumes, but we would like to extract technology T_n^j from these estimates. In order to do that, we follow the approach of Shikher (2004). In particular, for each country n , the share of total spending going to home-produced goods is given by

$$\frac{X_{nn}^j}{X_n^j} = T_n^j \left(\frac{\Gamma c_n^j}{p_n^j} \right)^{-\theta} .$$

Dividing by its U.S. counterpart yields:

$$\frac{X_{nn}^j/X_n^j}{X_{us,us}^j/X_{us}^j} = \frac{T_n^j}{T_{us}^j} \left(\frac{c_n^j p_{us}^j}{c_{us}^j p_n^j} \right)^{-\theta} = S_n^j \left(\frac{p_{us}^j}{p_n^j} \right)^{-\theta} ,$$

and thus the ratio of price levels in sector j relative to the U.S. becomes:

$$\frac{p_n^j}{p_{us}^j} = \left(\frac{X_{nn}^j/X_n^j}{X_{us,us}^j/X_{us}^j} \frac{1}{S_n^j} \right)^{\frac{1}{\theta}} . \quad (\text{B.1})$$

The entire right-hand side of this expression is either observable or estimated. Thus, we can impute the price levels relative to the U.S. in each country and each tradeable sector.

The cost of the input bundles relative to the U.S. can be written as:

$$\frac{c_n^j}{c_{us}^j} = \left(\frac{w_n}{w_{us}} \right)^{\alpha_j \beta_j} \left(\frac{r_n}{r_{us}} \right)^{(1-\alpha_j) \beta_j} \left(\prod_{k=1}^J \left(\frac{p_n^k}{p_{us}^k} \right)^{\gamma_{k,j}} \right)^{1-\beta_j} \left(\frac{p_n^{J+1}}{p_{us}^{J+1}} \right)^{\gamma_{J+1,j} (1-\beta_j)} .$$

Using information on relative wages, returns to capital, price in each tradeable sector from (B.1), and the nontradeable sector price relative to the U.S., we can thus impute the costs of the input bundles relative to the U.S. in each country and each sector. Armed with those values, it is

straightforward to back out the relative technology parameters:

$$\frac{T_n^j}{T_{us}^j} = S_n^j \left(\frac{c_n^j}{c_{us}^j} \right)^\theta.$$

B.2 Trade Costs

The bilateral, directional, sector-level trade costs of shipping from country i to country n in sector j are then computed based on the estimated coefficients as:

$$\ln \hat{d}_{ni}^j = \theta \hat{d}_k^j + \theta \hat{b}_{ni}^j + \theta \widehat{CU}_{ni}^j + \theta \widehat{RTA}_{ni}^j + \theta \widehat{ex}_i^j + \theta \widehat{v}_{ni}^j,$$

for an assumed value of θ . Note that the estimate of the trade costs includes the residual from the gravity regression $\theta \widehat{v}_{ni}^j$. Thus, the trade costs computed as above will fit bilateral sectoral trade flows exactly, given the estimated fixed effects. Note also that the exporter component of the trade costs $\widehat{ex}_i^j$ is part of the exporter fixed effect. Since each country in the sample appears as both an exporter and an importer, the exporter and importer estimated fixed effects are combined to extract an estimate of $\theta \widehat{ex}_i^j$.

B.3 Complete Estimation

So far we have estimated the levels of technology of the tradeable sectors relative to the United States. To complete our estimation, we still need to find (i) the levels of T for the tradeable sectors in the United States; (ii) the taste parameters ω_j , and (iii) the nontradeable technology levels for all countries.

To obtain (i), we use the NBER-CES Manufacturing Industry Database for the U.S. (Bartelsman and Gray 1996). We start by measuring the observed TFP levels for the tradeable sectors in the U.S.. The form of the production function gives

$$\ln Z_{us}^j = \ln \Lambda_{us}^j + \beta_j \alpha_j \ln L_{us}^j + \beta_j (1 - \alpha_j) \ln K_{us}^j + (1 - \beta_j) \sum_{k=1}^{J+1} \gamma_{k,j} \ln M_{us}^{k,j}, \quad (\text{B.2})$$

where Λ^j denotes the measured TFP in sector j , Z^j denotes the output, L^j denotes the labor input, K^j denotes the capital input, and $M^{k,j}$ denotes the intermediate input from sector k . The NBER-CES Manufacturing Industry Database offers information on output, and inputs of labor, capital, and intermediates, along with deflators for each. Thus, we can estimate the observed TFP level for each manufacturing tradeable sector using the above equation.

If the United States were a closed economy, the observed TFP level for sector j would be given by $\Lambda_{us}^j = (T_{us}^j)^{\frac{1}{\theta}}$. In the open economies, the goods with inefficient domestic productivity draws will not be produced and will be imported instead. Thus, international trade and competition introduce selection in the observed TFP level, as demonstrated by Finicelli, Pagano and Sbracia (2009a). We thus use the model to back out the true level of T_{us}^j of each tradeable sector in the United States. Here we follow Finicelli et al. (2009a) and use the following relationship:

$$(\Lambda_{us}^j)^\theta = T_{us}^j + \sum_{i \neq us} T_i^j \left(\frac{c_i^j d_{us,i}^j}{c_{us}^j} \right)^{-\theta}.$$

Thus, we have

$$(\Lambda_{us}^j)^\theta = T_{us}^j \left[1 + \sum_{i \neq us} \frac{T_i^j}{T_{us}^j} \left(\frac{c_i^j d_{us,i}^j}{c_{us}^j} \right)^{-\theta} \right] = T_{us}^j \left[1 + \sum_{i \neq us} S_i^j \left(d_{us,i}^j \right)^{-\theta} \right]. \quad (\text{B.3})$$

This equation can be solved for underlying technology parameters T_{us}^j in the U.S., given estimated observed TFP Λ_{us}^j , and all the S_i^j 's and $d_{us,i}^j$'s estimated in the previous subsection.

To estimate the taste parameters $\{\omega_j\}_{j=1}^J$, we use information on final consumption shares in the tradeable sectors in the U.S.. We start with a guess of $\{\omega_j\}_{j=1}^J$ and find sectoral prices p_n^k as follows. For an initial guess of sectoral prices, we compute the tradeable sector aggregate price and the nontradeable sector price using the data on the relative prices of nontradeables to tradeables. Using these prices, we calculate sectoral unit costs and Φ_n^j 's, and update prices according to equation (5), iterating until the prices converge. We then update the taste parameters according to equation (13), using the data on final sectoral expenditure shares in the U.S.. We normalize the vector of ω_j 's to have a sum of one, and repeat the above procedure until the values for the taste parameters converge.

Finally, we estimate the nontradeable sector TFP using the relative prices. In the model, the nontradeable sector price is given by

$$p_n^{J+1} = \Gamma(T_n^{J+1})^{-\frac{1}{\theta}} c_n^{J+1}.$$

Since we know the aggregate price level in the tradeable sector p_n^T , c_n^{J+1} , and the relative price of nontradeables (which we take from the data), we can back out T_n^{J+1} from the equation above for all countries.

NX_2^A (before, after)		(-0.30, -0.22)

Notes: This table presents the proportional changes (in percent) in welfare, the consumption price level expressed relative to the numeraire (wage in country 1), and the changes in relative wages, that come from a change in relative technology in country 1. The rows labeled “ NX_n^A (before, after)” for $n = 1, 2, 3$ report the net exports from country n in sector A relative to country n ’s GDP, before and after the technological change considered in the experiment. The top panel reports the changes due to moving from $T_1^A/T_1^B = 2$ to $T_1^A/T_1^B = 1$ while keeping $(T_1^A T_1^B)^{\frac{1}{2}} = 0.5$. The bottom panel reports the changes due to moving from $\{T_1^A = 0.5, T_1^B = 0.1\}$ to $\{T_1^A = 0.5, T_1^B = 0.5\}$. The other model parameters are described in the main text.

Table 2. Top and Bottom Trade Costs and Technological Similarity

Trade costs (average d_{ni}^j)			
Top 10 lowest		Top 10 highest	
Japan	1.638	Trinidad and Tobago	3.952
Korea, Rep.	1.653	Ghana	3.944
United States	1.699	Ethiopia	3.783
Malaysia	1.760	Senegal	3.777
Taiwan Province of China	1.784	Bolivia	3.639
Germany	1.846	Honduras	3.631
Australia	1.880	Jordan	3.614
Canada	1.890	Mauritius	3.506
United Kingdom	1.931	Nigeria	3.503
Indonesia	1.933	El Salvador	3.486

Technological similarity			
Top 10 highest		Top 10 lowest	
India	0.928	Sri Lanka	0.578
Turkey	0.907	Bolivia	0.592
Indonesia	0.904	Iceland	0.595
Hungary	0.897	Honduras	0.611
Brazil	0.896	El Salvador	0.654

mean	0.0054	0.0058
median	0.0002	0.0002
corr(model, data)	<i>0.902</i>	

Notes: This table reports the means and medians of wages relative to the U.S. (top panel); return to capital relative to the U.S. (second panel), share of domestically produced goods in overall spending (third panel), and share of goods from country i in overall spending (bottom panel) in the model and in the data. Wages and return to capital in the data are calculated as described in Section B.

Table 4. Welfare Changes

Panel A: Welfare Gains from Trade with China					
	Mean	Median	Min	Max	Countries
China	3.72				
OECD	0.13	0.12	-0.03	0.30	22
East and South Asia	0.23	0.20	-0.20	0.80	12
East. Europe and Cent. Asia	0.14	0.09	-0.08	0.78	11
Latin America and Caribbean	0.09	0.09	-0.27	0.39	15
Middle East and North Africa	0.12	0.13	0.04	0.22	6
Sub-Saharan Africa	0.08	0.06	-0.04	0.21	8
Panel B: Welfare Gains from Balanced Growth in China					
	Mean	Median	Min	Max	Countries
China	11.43				
OECD	0.01	0.02	-0.01	0.04	22
East and South Asia	0.03	0.04	-0.05	0.09	12
East. Europe and Cent. Asia	0.01	0.01	-0.02	0.06	11
Latin America and Caribbean	-0.01	0.00	-0.06	0.04	15
Middle East and North Africa	-0.01	-0.01	-0.07	0.02	6
Sub-Saharan Africa	0.00	0.01	-0.02	0.02	8
Panel C: Welfare Gains from Unbalanced Growth in China					
	Mean	Median	Min	Max	Countries
China	10.57				
OECD	0.17	0.12	-0.07	0.77	22
East and South Asia	0.84	0.74	0.22	1.70	12
East. Europe and Cent. Asia	0.42	0.34	0.07	1.52	11
Latin America and Caribbean	0.50	0.49	0.09	1.68	15
Middle East and North Africa	0.48	0.52	0.19	0.77	6
Sub-Saharan Africa	0.23	0.21	-0.03	0.57	8

Notes: Units are in percentage points. This table reports the changes in welfare from three counterfactual scenarios. Panel A presents the welfare gains in the benchmark for 2000s, relative to the scenario in which China is in autarky. Panel B presents the changes in welfare under the counterfactual scenario that growth is balanced in China across sectors, relative to the benchmark. Panel C presents the changes in welfare under the counterfactual scenario of unbalanced growth in China, relative to the benchmark. The technological changes assumed under the counterfactual scenarios are described in detail in the text.

Table 5. Welfare Changes, Unbalanced Trade

Panel A: Welfare Gains from Trade with China					
	Mean	Median	Min	Max	Countries
China	3.09				
OECD	0.30	0.27	0.04	0.89	22
East and South Asia	0.32	0.22	-0.29	1.92	12
East. Europe and Cent. Asia	0.44	0.32	0.03	0.99	11
Latin America and Caribbean	0.25	0.26	-0.36	1.13	15
Middle East and North Africa	0.80	0.49	0.18	2.37	6
Sub-Saharan Africa	0.63	0.55	0.10	1.95	8
Panel B: Welfare Gains from Balanced Growth in China					
	Mean	Median	Min	Max	Countries
China	11.56				
OECD	0.01	0.01	-0.01	0.04	22
East and South Asia	0.01	0.02	-0.09	0.07	12
East. Europe and Cent. Asia	0.00	0.00	-0.02	0.05	11
Latin America and Caribbean	-0.01	0.00	-0.09	0.03	15
Middle East and North Africa	-0.01	0.00	-0.08	0.02	6
Sub-Saharan Africa	0.00	0.00	-0.02	0.01	8
Panel C: Welfare Gains from Unbalanced Growth in China					
	Mean	Median	Min	Max	Countries
China	10.64				
OECD	0.14	0.12	-0.10	0.69	22
East and South Asia	0.83	0.76	0.23	1.69	12
East. Europe and Cent. Asia	0.36	0.36	0.09	0.83	11
Latin America and Caribbean	0.49	0.42	-0.20	1.49	15
Middle East and North Africa	0.43	0.44	0.18	0.69	6
Sub-Saharan Africa	0.22	0.25	-0.12	0.58	8

Notes: Units are in percentage points. This table reports the changes in welfare from three counterfactual scenarios under the assumption of unbalanced trade. Panel A presents the welfare gains in the benchmark for 2000s, relative to the scenario in which China is in autarky. Panel B presents the changes in welfare under the counterfactual scenario that growth is balanced in China across sectors, relative to the benchmark. Panel C presents the changes in welfare under the counterfactual scenario of unbalanced growth in China, relative to the benchmark. The technological changes assumed under the counterfactual scenarios are described in detail in the text.

Table 6. Welfare Changes, with Agriculture and Mining Sectors

Panel A: Welfare Gains from Trade with China					
	Mean	Median	Min	Max	Countries
China	3.53				
OECD	0.12	0.11	-0.04	0.31	22
East and South Asia	0.18	0.12	-0.26	0.69	12
East. Europe and Cent. Asia	0.06	0.07	-0.12	0.27	11
Latin America and Caribbean	0.04	0.04	-0.27	0.25	15
Middle East and North Africa	0.01	0.05	-0.16	0.13	6
Sub-Saharan Africa	0.08	0.09	-0.04	0.23	8
Panel B: Welfare Gains from Balanced Growth in China					
	Mean	Median	Min	Max	Countries
China	10.60				
OECD	0.01	0.02	-0.01	0.04	22
East and South Asia	0.02	0.03	-0.04	0.09	12
East. Europe and Cent. Asia	0.00	0.01	-0.03	0.04	11
Latin America and Caribbean	0.00	0.00	-0.05	0.02	15
Middle East and North Africa	0.01	0.01	-0.02	0.02	6
Sub-Saharan Africa	0.01	0.01	-0.02	0.02	8
Panel C: Welfare Gains from Unbalanced Growth in China					
	Mean	Median	Min	Max	Countries
China	8.59				
OECD	0.13	0.08	-0.09	0.59	22
East and South Asia	0.70	0.67	0.20	1.33	12
East. Europe and Cent. Asia	0.31	0.30	0.06	0.62	11
Latin America and Caribbean	0.39	0.41	0.05	0.99	15
Middle East and North Africa	0.51	0.59	0.11	0.68	6
Sub-Saharan Africa	0.28	0.26	-0.09	0.58	8

Notes: Units are in percentage points. This table reports the changes in welfare from three counterfactual scenarios in the model that includes Agriculture and Mining sectors in addition to manufacturing and nontradeables. Panel A presents the welfare gains in the benchmark for 2000s, relative to the scenario in which China is in autarky. Panel B presents the changes in welfare under the counterfactual scenario that growth is balanced in China across sectors, relative to the benchmark. Panel C presents the changes in welfare under the counterfactual scenario of unbalanced growth in China, relative to the benchmark. The technological changes assumed under the counterfactual scenarios are described in detail in the text.

Table 7. Welfare Changes, Direct Measures of Productivity

Panel A: Welfare Gains from Trade with China					
	Mean	Median	Min	Max	Countries
China	3.81				
OECD	0.15	0.14	-0.04	0.30	22
East and South Asia	0.22	0.18	-0.24	0.79	12
East. Europe and Cent. Asia	0.14	0.09	-0.13	0.71	11
Latin America and Caribbean	0.09	0.08	-0.28	0.38	15
Middle East and North Africa	0.11	0.13	0.02	0.22	6
Sub-Saharan Africa	0.07	0.05	-0.06	0.19	8
Panel B: Welfare Gains from Balanced Growth in China					
	Mean	Median	Min	Max	Countries
China	11.41				
OECD	0.01	0.02	-0.01	0.04	22
East and South Asia	0.02	0.03	-0.05	0.09	12
East. Europe and Cent. Asia	0.00	0.01	-0.02	0.05	11
Latin America and Caribbean	-0.01	0.00	-0.07	0.04	15
Middle East and North Africa	-0.01	-0.01	-0.06	0.02	6
Sub-Saharan Africa	0.00	0.00	-0.02	0.02	8
Panel C: Welfare Gains from Unbalanced Growth in China					
	Mean	Median	Min	Max	Countries
China	10.71				
OECD	0.17	0.14	-0.42	0.77	22
East and South Asia	0.86	0.73	0.21	1.68	12
East. Europe and Cent. Asia	0.43	0.41	-0.03	1.45	11
Latin America and Caribbean	0.50	0.44	0.08	1.68	15
Middle East and North Africa	0.45	0.50	0.19	0.77	6
Sub-Saharan Africa	0.23	0.21	-0.03	0.62	8

Notes: Units are in percentage points. This table reports the changes in welfare from three counterfactual scenarios. The productivity estimates used in this exercise are directly estimated using production data for 11 OECD countries. Panel A presents the welfare gains in the benchmark for 2000s, relative to the scenario in which China is in autarky. Panel B presents the changes in welfare under the counterfactual scenario that growth is balanced in China across sectors, relative to the benchmark. Panel C presents the changes in welfare under the counterfactual scenario of unbalanced growth in China, relative to the benchmark. The technological changes assumed under the counterfactual scenarios are described in detail in the text.

Table 8. Welfare Changes, $\theta = 4$

Panel A: Welfare Gains from Trade with China					
	Mean	Median	Min	Max	Countries
China	6.22				
OECD	0.26	0.25	-0.04	0.64	22
East and South Asia	0.49	0.43	-0.42	1.56	12
East. Europe and Cent. Asia	0.30	0.21	-0.13	1.50	11
Latin America and Caribbean	0.20	0.22	-0.40	0.72	15
Middle East and North Africa	0.34	0.30	0.13	0.57	6
Sub-Saharan Africa	0.19	0.14	0.01	0.41	8
Panel B: Welfare Gains from Balanced Growth in China					
	Mean	Median	Min	Max	Countries
China	13.51				
OECD	0.03	0.04	-0.01	0.08	22
East and South Asia	0.07	0.10	-0.05	0.19	12
East. Europe and Cent. Asia	0.03	0.02	-0.02	0.16	11
Latin America and Caribbean	0.01	0.01	-0.07	0.08	15
Middle East and North Africa	0.01	0.02	-0.06	0.06	6
Sub-Saharan Africa	0.03	0.02	0.00	0.06	8
Panel C: Welfare Gains from Unbalanced Growth in China					
	Mean	Median	Min	Max	Countries
China	6.60				
OECD	0.22	0.18	-0.13	0.74	22
East and South Asia	1.11	1.00	0.32	2.41	12
East. Europe and Cent. Asia	0.57	0.49	0.10	1.64	11
Latin America and Caribbean	0.52	0.48	0.04	1.46	15
Middle East and North Africa	0.63	0.70	0.28	0.89	6
Sub-Saharan Africa	0.29	0.24	-0.05	0.82	8

Notes: Units are in percentage points. This table reports the changes in welfare from three counterfactual scenarios. The model is estimated, solved, and simulated under the assumption that $\theta = 4$. Panel A presents the welfare gains in the benchmark for 2000s, relative to the scenario in which China is in autarky. Panel B presents the changes in welfare under the counterfactual scenario that growth is balanced in China across sectors, relative to the benchmark. Panel C presents the changes in welfare under the counterfactual scenario of unbalanced growth in China, relative to the benchmark. The technological changes assumed under the counterfactual scenarios are described in detail in the text.

Table 9. Welfare Changes, Sector-Specific θ_j 's

Panel A: Welfare Gains from Trade with China					
	Mean	Median	Min	Max	Countries
China	3.30				
OECD	0.22	0.20	-0.02	0.44	22
East and South Asia	0.46	0.49	-0.13	1.02	12
East. Europe and Cent. Asia	0.28	0.15	0.05	0.75	11
Latin America and Caribbean	0.25	0.27	-0.20	0.65	15
Middle East and North Africa	0.44	0.49	0.19	0.71	6
Sub-Saharan Africa	0.63	0.63	0.07	1.32	8
Panel B: Welfare Gains from Balanced Growth in China					
	Mean	Median	Min	Max	Countries
China	15.36				
OECD	0.01	0.02	-0.06	0.05	22
East and South Asia	0.00	0.01	-0.19	0.16	12
East. Europe and Cent. Asia	-0.04	0.00	-0.21	0.02	11
Latin America and Caribbean	-0.04	-0.05	-0.16	0.05	15
Middle East and North Africa	-0.08	-0.10	-0.12	-0.01	6
Sub-Saharan Africa	-0.10	-0.10	-0.24	0.01	8
Panel C: Welfare Gains from Unbalanced Growth in China					
	Mean	Median	Min	Max	Countries
China	9.68				
OECD	0.05	0.06	-0.37	0.43	22
East and South Asia	0.56	0.68	-0.46	1.50	12
East. Europe and Cent. Asia	0.19	0.19	-0.23	0.51	11
Latin America and Caribbean	0.27	0.26	-0.31	0.99	15
Middle East and North Africa	0.18	0.21	-0.19	0.39	6
Sub-Saharan Africa	0.06	0.12	-0.41	0.50	8

Notes: Units are in percentage points. This table reports the changes in welfare from three counterfactual scenarios. The model is estimated, solved, and simulated under the assumption that θ_j 's are sector-specific. The values of θ_j are sourced from Caliendo and Parro (2010). Panel A presents the welfare gains in the benchmark for 2000s, relative to the scenario in which China is in autarky. Panel B presents the changes in welfare under the counterfactual scenario that growth is balanced in China across sectors, relative to the benchmark. Panel C presents the changes in welfare under the counterfactual scenario of unbalanced growth in China, relative to the benchmark. The technological changes assumed under the counterfactual scenarios are described in detail in the text.

Figure 1. Chinese Trade, 1962-2007

(a) China and World Trade, Index Number, 1990=100

(b) Share of Imports from China in Total Imports, by Region

Notes: Figure 1(a) plots the total real (inflation-adjusted) exports from China (solid line), and the total real (inflation-adjusted) world exports (dashed line), for the period 1962-2007. Both series are normalized such that the 1990 value equals 100. Figure 1(b) plots the share of imports coming from China in the total imports of the major world regions, 1962-2007.

Figure 2. Welfare and Technological Similarity: A Numerical Example

(a) 2-Country Model

(b) 3-Country Model

Notes: This figure plots welfare in country 1 and country 2 as a function of T_1^A/T_1^B . The top panel considers a 2-country model, whereas the bottom panel a 3-country model. For country 2, $T_2^A/T_2^B = 1$, so countries 1 and 2 have the same technology when the value on the x-axis equals 1. Exact parameter values are described in Section 2.3.

Figure 3. Benchmark Model vs. Data: π_{ni}^j for China and the Rest of the Sample

Notes: This figure displays the model-implied values of π_{ni}^j on the y-axis against the values of π_{ni}^j in the data on the x-axis. Solid red dots depict π_{ni}^j in which either n or i equals China. Hollow dots represent the non-China π_{ni}^j 's. The line through the points is the 45-degree line.

Figure 4. Gains from Trade with China

(a) Country's Export Pattern and China's Export Pattern

(b) Country's Export Pattern and China's Import Pattern

(c) Country's Import Pattern and China's Export Pattern

Notes: This figure reports the partial correlation plots between the gains from trade with China on the y-axis against the indicator on the x-axis. The units on the y-axis are percentage points. In each plot, the other two indicators, log average d_{ni}^j , and log population are the control variables. The R^2 of the regression that includes all variables is 0.38.

Figure 5. China: Actual and Counterfactual Productivities

Notes: This figure displays the actual and counterfactual productivities in China, by sector. The key for sector labels is reported in Table A2. The formula for the balanced counterfactual T 's is: $(T_n^j)_{\text{balanced}} = (T_n^j)_{2000s} \times g_T$, where $g_T = \left(\prod_{k=1}^J (T_n^k / T_F^k)_{2000s} \right)^{\frac{1}{J}} / \left(\prod_{k=1}^J (T_n^k / T_F^k)_{1990s} \right)^{\frac{1}{J}}$ is the growth rate of the average productivity relative to world frontier between the 1990s and the 2000s, with T_F^j the world frontier productivity in sector j , calculated as the geometric average of the top two values of T_n^j in the world. The formula for the unbalanced counterfactual T 's is $(T_n^j)_{\text{unbalanced}} = (T_F^j)_{2000s} \times \left(\prod_{k=1}^J (T_n^k / T_F^k)_{2000s} \right)^{\frac{1}{J}} \times g_T$.

Figure 6. Welfare Gains in the Balanced and Unbalanced Counterfactuals

(a) Endogenous Factor Prices

(b) Fixed Factor Prices

Notes: This figure displays the scatterplots of the welfare gains in the balanced counterfactual on the y-axis against the welfare gain in the unbalanced counterfactual on the x-axis. The units on all of the axes are percentage points. The top panel reports the results from the complete model in which the factor prices w and r adjust to clear goods and factor markets. The bottom panel reports the welfare changes under the assumption that w and r remain constant at their baseline values. The 45-degree line is added to both plots.

Figure 7. China's and World Average Comparative Advantage

Notes: This figure displays the distance to the global frontier in each sector in China (y-axis) against the simple average of the distance to frontier in that sector in the world excluding China. The key for sector labels is reported in Table A2.

Figure 8. Welfare Gains Under Fixed and Endogenous Factor Prices

(a) Balanced Counterfactual

(b) Unbalanced Counterfactual

Notes: This figure displays the scatterplots of the welfare gains under fixed factor prices on the x-axis against the welfare gains under endogenous factor prices on the y-axis in the balanced counterfactual (top panel) and the unbalanced counterfactual (bottom panel). The units on all of the axes are percentage points. The 45-degree line is added to both plots.

Figure 9. Unbalanced Counterfactual Welfare Gains and Technological Similarity

(a) Endogenous Factor Prices

(b) Fixed Factor Prices

Notes: This figure displays the scatterplots of the welfare gains in the unbalanced counterfactual on the y-axis against the change in the technological between the country and China. The units on the y-axis are percentage points. Technological similarity is measured as the correlation coefficient of the T's between the country and China. On the y-axis is the simple change in that correlation coefficient. The top panel reports the results from the complete model in which the factor prices w and r adjust to clear goods and factor markets. The bottom panel reports the welfare changes under the assumption that w and r remain constant at their baseline values. The OLS best fit line is added to both plots.

Table A1. Country Coverage and Welfare Changes in the Main Counterfactuals

Country	Δ Welfare		Country	Δ Welfare	
	Balanced	Unbalanced		Balanced	Unbalanced
<u>OECD</u>			<u>East and South Asia</u>

26	Non-Metallic Mineral Products	0.365	0.459	0.499	0.071
27	Basic Metals	0.381	0.299	0.451	0.002
28	Fabricated Metal Products	0.448	0.398	0.364	0.012
29C	Office, Accounting, Computing, and Other Machinery	0.473	0.390	0.388	0.094
31A	Electrical Machinery, Communication Equipment	0.405	0.380	0.416	0.057
33	Medical, Precision, and Optical Instruments	0.456	0.428	0.441	0.036
34A	Transport Equipment	0.464	0.343	0.286	0.175
36	Furniture and Other Manufacturing	0.460	0.407	0.397	0.065
4A	Nontradeables	0.561	0.651	0.788	
	Mean	0.414	0.393	0.399	0.053
	Min	0.244	0.243	0.246	0.002
	Max	0.561	0.651	0.788	0.209

Notes: This table reports the sectors used in the analysis. The classification corresponds to the ISIC Revision 3 2-digit, aggregated further due to data availability. α_j is the value-added based labor intensity; β_j is the share of value added in total output; $\gamma_{J+1,j}$ is the share of nontradeable inputs in total intermediate inputs; ω_j is the taste parameter for tradeable sector j , estimated using the procedure described in Section B.3. Variable definitions and sources are described in detail in the text.

Table A3. Alternative Counterfactuals

Panel A: Summary Statistics					
	Mean	St. Dev.	Min	Max	
Balanced	0.01	0.03	-0.07	0.09	
Unbalanced	0.42	0.39	-0.07	1.70	
Unbalanced – Linear	0.11	0.12	-0.02	0.56	
Unbalanced – No Regress	0.28	0.28	-0.06	1.28	
Unbalanced – U.S. Values	0.43	0.42	-0.10	1.89	
Unbalanced – VA-Weighted	0.44	0.41	-0.06	1.82	
Panel B: Correlations					
	Balanced	Unbalanced	Unbalanced – Linear	Unbalanced – No Regress	Unbalanced – U.S. Values
Balanced	1.000				
Unbalanced	0.065	1.000			
Unbalanced – Linear	-0.157	0.946	1		
Unbalanced – No Regress	0.131	0.984	0.9394	1.000	
Unbalanced – U.S. Values	0.054	0.997	0.9368	0.973	1.000
Unbalanced – VA-Weighted	0.082	1.000	0.9423	0.984	0.995

Notes: The top panel of this table reports the summary statistics for the different counterfactual scenarios for Chinese productivity growth. “Balanced” and “Unbalanced” are the two main counterfactuals in the paper, depicted graphically in Figure 5. “Unbalanced – Linear” is a counterfactual in which the most productive Chinese sector relative to the world frontier keeps the same productivity, while each successive sectors’s productivity relative to the world frontier is lower by a fixed multiplicative constant. “Unbalanced – No Regress” is a counterfactual in which productivity in each Chinese sector becomes a constant ratio to the world frontier, unless that would imply an absolute reduction in sectoral productivity, in which case the productivity remains unchanged. “Unbalanced – U.S. Values” is a counterfactual in which Chinese productivity relative to the world frontier is the same as in the U.S. Across all counterfactuals, the geometric average sectoral productivity in Chinese sectors is kept the same. These three counterfactuals are depicted graphically in Figure A1. The “Unbalanced – VA-Weighted” counterfactual is designed so that the value-added-weighted (rather than unweighted) geometric average productivity growth is the same in the unbalanced counterfactual as in the balanced one.

Figure A1. China: Alternative Counterfactual Productivities

Notes: This figure displays the sectoral productivities under three alternative unbalanced counterfactual scenarios in China. The construction of the three scenarios is described in detail in the text. The key for sector labels is reported in Table A2.
