## ABSTRACT

---

We construct a new dataset using census, survey, and registry data from hundreds of sources to document a clear positive relationship between aggregate productivity and average establishment size in manufacturing across 134 countries. We rationalize this relationship using a standard model of reallocation among production units that features endogenous entry and productivity investment. The model connects small operational scales to the prevalence in poor countries of correlated distortions (the elasticity between wedges and establishment productivity). The model also rationalizes the finding in poor countries of low establishment-level productivity and low aggregate productivity investment. A calibrated version of the model implies that when correlated distortions change from 0.09 in the U.S. to 0.5 in India, establishment size and productivity fall by a factor of more than five, and aggregate productivity by a factor of three. These substantial size and productivity losses are large compared to the existing literature and more in line with actual data for the differences in size and productivity between India and the United States.

---

Keywords: misallocation, establishment size, productivity, investment, idiosyncratic distortions.

JEL codes: O1, O4.

# 1 Introduction

A consensus view in the literature has emerged where the large variations in income per capita across countries are mostly explained by differences in total factor productivity (TFP). A potential explanation for these productivity differences is the (mis)allocation of factors of production among heterogeneous production units that differs across countries. An important finding in the empirical literature on misallocation is that not only is there evidence of large aggregate effects from misallocation across heterogeneous production units (e.g. Hsieh and Klenow, 2009), but also that there are substantial cross-country differences in existing establishment-level productivity (e.g., Hsieh and Klenow, 2009; Pagés-Serra, 2010; Gal, 2013). What explains the differences in establishment-level and aggregate productivity across countries? We address this question through a standard model of reallocation with heterogeneous production units that features an investment decision on establishment-level productivity and an entry decision. The model connects two pieces of empirical evidence which we document—the prevalence of correlated distortions and the smaller operational scale of production units in poor countries—to explain low establishment-level productivity and hence low aggregate productivity. The contribution of low establishment productivity to aggregate productivity is in addition to the standard effect of factor misallocation on aggregate productivity.

Evidence of the relationship between development and establishment size has been both sparse and inconclusive due to the lack of standardized size data for a large group of countries.<sup>1</sup> We address this by constructing a standardized database on establishment and firm sizes based on individual-country data from manufacturing censuses, surveys, and registries. Using hundreds of separate sources, we have assembled data for 134 countries with comparable employment-size data. In contrast to Alfaro et al. (2009) and Bollard et al. (2014), who use international data plagued by cross-country differences in the size of sampled firms, we show that average establishment size is strongly positively correlated with GDP per capita. For instance, whereas

---

<sup>1</sup>Poschke (2014) reports a positive relationship between size and development, while Alfaro et al. (2009) and Bollard et al. (2014) find the opposite relationship. We discuss this further in Section 2.

average establishment size in U.S. manufacturing is 22 workers, in Benin and Sierra Leone it is about 2 workers, an 11-fold difference. As a summary measure of the relationship between development and size, we compute the income elasticity of establishment size to be 0.29. Large differences in operational scales are also found in other sectors such as agriculture from Census data where the operational scale of farms in rich countries is 34 times that of poor countries (see for instance Adamopoulos and Restuccia, 2014). Our data confirms the finding in Poschke (2014) where survey data on entrepreneurs and financial data for large firms are shown to imply a similar positive income elasticity of size across 43 countries.

We consider a standard model of heterogeneous production units that builds from Hopenhayn (1992). For comparability, the setup follows closely the monopolistic competition framework used in the empirical analysis of Hsieh and Klenow (2009). The basic framework is extended along two important dimensions in order to address differences in entry and establishment-level productivity. We incorporate an endogenous entry decision of establishments as well as an endogenous investment decision on establishment-level productivity by entrants. There is a large number of potential entrants that draw their idiosyncratic productivity from a known distribution at a cost. Establishments can invest in their productivity at a cost but only before the realization of their idiosyncratic productivity. In the theory, ex-ante identical entering establishments make the same productivity investment decision but are ex-post heterogeneous in their idiosyncratic productivity. The theory connects policy distortions, institutions, and frictions that discourage establishment-level investment. The key emphasis in the model is the extent to which distortions that effectively penalize more productive relative to less productive establishments—what Restuccia and Rogerson (2008) call correlated idiosyncratic distortions, discourage productivity investment by all establishments. The set of policies and institutions that effectively create correlated idiosyncratic distortions is very large and has been extensively discussed in the literature, see for instance Restuccia and Rogerson (2013) and Hopenhayn (2014). In the model, we show there is a strong connection between the extent of correlated distortions, establishment-level productivity, and the mass of entrants in the economy. These

effects work to lower establishment size, establishment-level productivity, and aggregate productivity. By staying close to Hsieh and Klenow (2009), we are able to explicitly decompose the effects of distortions into those working through the investment channel emphasized in this paper, and those working through the factor misallocation channel analyzed in Hsieh and Klenow (2009).

We calibrate a benchmark economy to U.S. data and show that reasonable variations in the extent of correlated distortions have substantial negative effects on establishment size, establishment-level productivity, and aggregate output per capita. In order to provide a quantitative assessment of this channel in explaining productivity differences across countries, we first document evidence from cross-country micro data for the elasticity between distortions (wedges) and establishment productivity, using establishment-level data from the World Bank's Enterprise Surveys. We show that the elasticity of distortions with respect to productivity in the micro data is strongly negatively related to both average establishment size and GDP per capita across 63 countries. We then evaluate the quantitative implications of the observed measures of correlated distortions in the model for establishment size and productivity. Our results are striking. Compared to the calibrated U.S. benchmark economy, increasing correlated distortions to 0.5 (the elasticity between wedges and establishment productivity found for India) generates a reduction in establishment size to 2.8 workers versus the 22 workers in the U.S. economy, and a similar reduction in establishment-level productivity. The 1.6-fold difference in aggregate productivity between the U.S. and India generated by factor misallocation in Hsieh and Klenow (2009) is also amplified in this paper into a 3-fold difference. These are large size and productivity losses compared to the existing literature in misallocation and development and are more in line with the observed size and productivity differences between the U.S. and India.

We emphasize that with no endogenous investment in productivity, the model would imply no differences in establishment size and productivity from misallocation. As a result, this channel

not only amplifies the losses in output and productivity from misallocation, but also rationalizes the impact of distortions on establishment size as observed in the cross-country data. See for instance the related work of Hopenhayn (2013) emphasizing the potential importance of establishment size in generating substantial differences in productivity from specific distortionary policies. To the extent that misallocation is reduced within a country over time, the model also contributes to understanding trends in establishment size. In the United States, for example, Poschke (2014) reports a doubling of average firm size since the early twentieth century, while the results in Ziebarth (2013) and Hsieh and Klenow (2009) suggest a significant reduction in misallocation in the U.S. over the same time period.

Our paper is closely related to the broad literature on misallocation and productivity.<sup>2</sup> In particular, within this literature we relate to papers studying the impact of policies and institutions generating misallocation that also induce disincentives for establishments to invest in productivity. Early examples of this literature are Restuccia (2013a) and Bello et al. (2011) with more elaborate analysis in Ranasinghe (2014), Bhattacharya et al. (2013), Gabler and Poschke (2013), and Da-Rocha et al. (2014), among others. The closest paper to ours is Hsieh and Klenow (2014) since our modeling of correlated distortions follows theirs closely. Hsieh and Klenow (2014) introduce correlated distortions into an economy where establishments invest in step-by-step innovation, and generate qualitative implications similar to ours. By modeling productivity investment in a more parsimonious way, we are able to derive closed-form expressions for the impact of correlated distortions on establishment size and aggregate TFP through the investment channel. This allows us to analyze the source of the dramatic quantitative differences between the effects of correlated distortions in this paper and those in Hsieh and Klenow (2014). One contribution of our paper is to isolate the effects of distortions working through the investment and factor misallocation channels, disentangling them from the effects of various other distortions present in Hsieh and Klenow (2014).

---

<sup>2</sup>See for instance the surveys of this literature in Restuccia and Rogerson (2013), Restuccia (2013b), and Hopenhayn (2014).

In generating differences in establishment size, our work is closely related to the seminal work of Lucas (1978) who showed that an elasticity of substitution less than one may be needed in the production function between capital and labor in order to rationalize the larger operational scales in rich countries. In our framework, even with Cobb-Douglas technology, establishment size can vary with correlated distortions. The view that differences in size across countries can arise from distortions shares with the work of Guner et al. (2008) who emphasize size-dependent distortions, i.e., distortions such as taxes and regulations that apply only beyond a threshold size in terms of the number of workers in the firm. We differ from Guner et al. in that in our framework any correlated distortion causes productivity at the establishment level to drop for all establishments, adding to the potential factor misallocation effects typically emphasized in the literature. For this reason, the size and productivity impact of correlated distortions in our framework are orders of magnitude larger than those emphasized in Guner et al. (2008). The literature has also explored many specific policies thought to explain income differences across countries such as firing costs, entry costs, or average tax rates that lead to larger establishment sizes in poor countries (e.g., Hopenhayn and Rogerson, 1993; Barseghyan and DiCecio, 2011; Moscoso Boedo and Mukoyama, 2012; among others). To the extent that poor countries have both harmful policies *and* correlated distortions, this paper helps to rationalize why establishments are smaller in countries with higher average costs of doing business.

The paper is organized as follows. In the next section, we present the facts from our constructed dataset of 134 countries to establish that establishment size increases substantially with the level of development across countries. Section 3 presents the model and characterizes the qualitative implications. In Section 4, we calibrate the model to data for the United States and show the quantitative implications of the model for hypothetical variations in the extent of correlated distortions. We then construct and document measures of correlated distortions across countries and assess their potential to generate differences in size and productivity. We also discuss our results for reasonable extensions in the model and reasonable variations in key parameter values. We conclude in Section 5.

## 2 Average Establishment Size Across Countries

We construct a dataset for the average employment size of manufacturing establishments and firms across countries between 2000 and 2012 using hundreds of economic censuses and surveys which use comprehensive business registries to create sampling frames.<sup>3</sup> We include all countries with publicly available data representative of all manufacturing establishments or firms.<sup>4</sup> Not included in the data are businesses without a fixed location. Businesses operating out of households are generally included only if signs are posted on the premises.<sup>5</sup>

Our standardized definition of size is the average number of persons engaged per establishment (defined as a physical location where economic activity takes place), but different countries report statistics using different definitions. Some countries report the number of active establishments and firms (where a firm is a collection of establishments under common ownership), while other countries report only one or the other. Three definitions of employment are also used: persons engaged (paid and unpaid), average number of employees (including full-time and part-time paid workers), and full-time equivalent employees. In the appendix we explain in detail how we use these data to construct our standardized measure. Throughout the data-collection process, we have made an effort to search for evidence from methodology documents and other published reports that small establishments are not included. Any country for which such evidence exists is not included in our sample.

It is worth digressing at this point to note that accounting for establishments without paid employees is crucial when investigating differences in establishment size across rich and poor countries, as these establishments (which often employ unpaid family members) account for a

---

<sup>3</sup>In the appendix we provide greater detail about how we construct the dataset, a list of the countries included, and a list of the sources we use for each country.

<sup>4</sup>The dataset also includes all territories such as French Guiana, Hong Kong, and Puerto Rico. We use the word ‘country’ solely for ease of exposition.

<sup>5</sup>The sole exception to this rule is the United States. Although U.S. employer data uses a standard definition of ‘establishment,’ the data for non-employers (i.e., self-employed) includes businesses with no fixed location like food trucks or sub-contractors in construction. Our focus on manufacturing should prevent this from being an issue, but our reported employment size for the U.S. may as a result be slightly biased downwards.

significant portion of establishments in poor countries. In Sierra Leone, for example, 83 percent of establishments have no paid employees, and in Ghana, unpaid workers account for almost half of the manufacturing workforce. As a result, excluding non-employer establishments would generate a highly distorted picture of cross-country establishment size differences.

In our final dataset, persons engaged per establishment is averaged over all years for each of the 134 countries.<sup>6</sup> Table 1 reports some descriptive statistics concerning average establishment size, GDP per capita, and population.<sup>7</sup>

Table 1: DESCRIPTIVE STATISTICS

|                            | Mean | Median | Poorest<br>Decile | Richest<br>Decile |
|----------------------------|------|--------|-------------------|-------------------|
| Establishment Size         | 12   | 9      | 6                 | 19                |
| GDP per capita (thousands) | 18   | 13     | 1.2               | 55                |
| Population (millions)      | 32   | 6      | 28                | 25                |

Notes: ‘Poorest’ and ‘richest’ refer to GDP per capita. Data from multiple sources, see text for details.

Figure 1 shows average establishment size for 134 countries in relation to GDP per capita. The data clearly show a positive correlation between average establishment size and GDP per capita. In particular, the elasticity of establishment size with respect to GDP per capita is 0.29. Figure 2 shows that the correlation between size and income is even stronger if we omit small countries with populations less than half of one million. In this case, the elasticity rises to 0.35. Each of these elasticities is remarkably robust to controlling for openness to trade and quality of institutions.<sup>8</sup> Recent models linking market size and markups predict that both

<sup>6</sup>Although size data is available for Norfolk Island, it has been dropped for lack of any reliable measure of GDP per capita.

<sup>7</sup>GDP per capita (adjusted for purchasing power parity, PPP) is from Penn World Table v. 8.0 for 105 countries, the IMF’s World Economic Outlook 2013 for 7 countries, and the CIA World Factbook for 17 countries. For four countries (actually overseas departments of France), GDP per capita is from France’s National Institute of Statistics and Economic Studies and is made relative to the U.S. GDP per capita using market exchange rates. GDP per capita for Åland Islands is from Statistics and Research Åland, and adjusted for purchasing power parity using Finland’s PPP exchange rate from Penn World Table v. 8.0. Population data is from Penn World Table v. 8.0 (105 countries), the World Bank’s World Development Indicators (21 countries), the CIA World Factbook (7 countries), and Statistics and Research Åland (for Åland Islands).

<sup>8</sup>Our measure of openness to trade is from Penn World Table v. 8.0. Our measure of institutional quality is

Figure 1: Establishment Size and GDP per Capita

GDP per capita and establishment size should increase with population, suggesting that the relationship illustrated in Figures 1 and 2 could be explained by differences in population size across countries.<sup>9</sup> But Figure 3 shows that establishment size is not systematically related to population.<sup>10</sup>

To confirm that the observed relationship between establishment size and GDP per capita is not being driven by how the establishment size data is constructed, we separately test the relationship between size and GDP for persons engaged per establishment, persons engaged per firm, employees per establishment, and employees per firm, using only the unadjusted source data for each country. The corresponding elasticities are all positive and of comparable magnitude: 0.38, 0.34, 0.32, and 0.28.<sup>11</sup>

We now compare the implications of our data relative to the existing work in the literature.

A widely cited reference for the relationship between firm size and income is Alfaro et al.

the Heritage Foundation's Index of Economic Freedom (2014).

<sup>9</sup>Melitz and Ottaviano (2008) and Desmet and Parente (2012), for example, each develop models in which larger populations can lead to both higher output per capita and larger establishments.

<sup>10</sup>The regression slope coefficient (standard error) in Figure 1 is 0.29 (0.04) and in Figure 2 is 0.35 (0.04). In Figure 3 the slope coefficient is insignificant -0.003 (0.03).

<sup>11</sup>The corresponding number of observations in each regression are 64, 48, 45, and 52.

Figure 2: Establishment Size and GDP per Capita (small countries removed)

Figure 3: Establishment Size and Population

(2009). They use Dun & Bradstreet’s WorldBase data (DB) to document a negative relationship between firm size and income per capita across 79 countries. More recently, Bollard et al. (2014) report the same negative relationship using data from the United Nations Industrial Development Organization’s (UNIDO) Industrial Statistics Database for 72 countries. These observations are in direct contrast to those just documented from our data. They are also opposite to the relationship found for specific sectors such as agriculture where census data indicates much smaller farm size operation in poor countries relative to rich (see for instance Adamopoulos and Restuccia, 2014). To understand Alfaro et al., it useful to first emphasize that DB is comprised of business data aggregated from multiple sources that is typically used to provide credit and market-assessment services. A key issue is that DB has sparse coverage of small firms in poor countries relative to rich countries, with no attempt to make the data representative of all establishments. As a result, when calculating average establishment size in poor countries, the under-representation of small firms biases the average upwards. In a sense, Alfaro et al. are comparing average size across most establishments in rich countries with the average size of only large establishments in poor countries. The UNIDO data used by Bollard et al. similarly include countries with unbalanced populations of establishments, with some countries reporting data for all establishments and other countries reporting data only for larger establishments.<sup>12</sup> More importantly, our data contains information for 59 countries from Alfaro et al.’s sample and 59 countries from Bollard et al.’s sample, and the result of a positive relationship between establishment size and development is even stronger in these subsamples than for all 134 countries.

Poschke (2014) finds that firm and establishment size are strongly increasing in development, consistent with our evidence. Poschke uses two datasets, one from Global Entrepreneurship Monitor for small and medium firms in 47 countries, and one from Amadeus for large firms in 34 countries. Unlike Alfaro et al. (2009) and Bollard et al. (2014), the survey data used in Poschke is constructed in such a way as to be representative of all firms (within each size class)

---

<sup>12</sup>For this reason, some of the countries used in Bollard et al. (2014) have been excluded from our dataset.

for each country. Although his sample of countries is smaller, Poschke is able to show that size is increasing in development across multiple sectors of the economy.

Comparing the results of our analysis with those of Alfaro et al. (2009), Bollard et al. (2014), and Poschke (2014) makes it clear that analyzing standardized, representative size data, especially with respect to the smallest establishments in poor countries, is crucial to obtaining clear evidence of the relationship between development and average employment size of establishments across countries.

### 3 The Model

Consider an economy where time is discrete and indexed by  $t$ . A representative final-good firm uses a variety of imperfectly substitutable inputs from intermediate-good firms to produce the final consumption good.<sup>13</sup> There is a stand-in household endowed with a continuum of members (of measure one), each supplying one unit of labor each period. There are a large number of potential intermediate firms who are free to enter, but must pay a fixed entry cost and make a costly productivity-investment decision before producing. Firms face output distortions which may be correlated with firm-level productivity. Entrants take policy distortions into account when investing in productivity. We assume an exogenous probability of exit and, as a result, there is ongoing entry and exit in steady state. We study the decentralized equilibrium of the economy in which firms take the wage, the interest rate, and the size of the economy as given, and free entry ensures the value of entry is driven to zero. We then consider how the extent of correlated distortions affects the number of firms, investment, and aggregate output.<sup>14</sup> We begin by describing the environment in more detail.

---

<sup>13</sup>Throughout we use ‘firm’ and ‘establishment’ interchangeably in reference to intermediate-good firms.

<sup>14</sup>We refer to the ‘mass’ of firms as the ‘number’ of firms for ease of exposition.

### 3.1 Environment

The representative final-good firm produces output using a variety of inputs from intermediate-good firms according to the following production function;

$$Y = \left( \int_0^N y_i^{\frac{\sigma-1}{\sigma}} di \right)^{\frac{\sigma}{\sigma-1}},$$

where  $N$  is the number of intermediate-good firms,  $y_i$  the demand for input  $i$ , and  $\sigma$  the constant elasticity of substitution between varieties.

Each intermediate-good firm has access to the following production function;

$$y = sz\ell,$$

where  $sz$  is productivity and  $\ell$  is labor. An entrant's realized  $z$  is drawn from a known exogenous distribution, while  $s$  is chosen by the entrant before realizing  $z$ . After paying an entry cost  $c_e Y$ , an entrant chooses  $s$  by incurring a cost equal to  $c_s Y s^\theta$ , where both  $c_s > 0$  and  $\theta > 1$  are exogenous and common to all firms.<sup>15</sup> At the end of each period, each intermediate producer faces an exogenous probability of exit equal to  $\lambda$ .

Output distortions are such that each firm retains a fraction  $(1 - \tau)$  of its output, and we assume  $\tau$  depends on firm-level productivity as follows;

$$(1 - \tau_i) = (s_i z_i)^{-\gamma},$$

where the parameter  $\gamma$  is the elasticity of a firm's distortion with respect to its productivity.

Given our assumptions, each firm will choose the same  $s$  in equilibrium, all entrants will choose

---

<sup>15</sup>Our specification of entry costs is consistent with Bollard et al. (2014), who argue using time-series data that entry costs should scale up with secular development. Note that if population were not normalized to one, we would need to make the entry and investment costs scale up with output per capita.

to continue operating, and the distribution of productivities across firms will remain invariant. We abstract from the household's intertemporal consumption decision and simply assume an exogenous interest rate  $R$ .

## 3.2 Equilibrium

We focus on the steady-state decentralized equilibrium of the economy in which the distributions of prices and allocations are invariant. A *steady-state decentralized equilibrium* is defined as a wage rate  $w$ , distributions of firm-level productivities  $sz$ , intermediate-good prices  $P$ , output  $y$ , labor demand  $\ell$ , and profits  $\pi$ , a number of firms  $N$ , and aggregate output  $Y$ , such that;

- (i) given each  $P$ , the final-good firm demands intermediate-good inputs to maximize profits in each period,
- (ii) given  $w$ ,  $R$ , and  $Y$ , intermediate-good producers choose labor to maximize per-period profits,
- (iii) given  $w$ ,  $R$ , and  $Y$ , entrants choose productivity to maximize the expected present value of lifetime profits,
- (iv) free entry ensures the expected present value of lifetime profits for an entrant is equal to the optimal productivity investment plus the entry cost,
- (v) markets clear, i.e., the supply of labor (equal to one) is equal to the quantity of labor demanded by firms.

The final-good firm takes input prices as given and maximizes profits in each period, generating the following inverted demand function for each input  $i$ ;

$$P_i = Y^{\frac{1}{\sigma}} y_i^{\frac{-1}{\sigma}}.$$

Profits in each period for an incumbent firm- $i$  are therefore;

$$\pi_i = (1 - \tau_i)Y^{\frac{1}{\sigma}}y_i^{\frac{\sigma-1}{\sigma}} - w\ell_i, \quad \text{where} \quad y_i = s_i z_i \ell_i.$$

Firms choose labor to maximize profits each period, generating the following demand for labor and optimal output;

$$\begin{aligned} \ell_i &= \frac{(1 - \tau_i)^\sigma Y (s_i z_i)^{\sigma-1}}{w^\sigma} \left( \frac{\sigma - 1}{\sigma} \right)^\sigma, \\ y_i &= \frac{(1 - \tau_i)^\sigma Y (s_i z_i)^\sigma}{w^\sigma} \left( \frac{\sigma - 1}{\sigma} \right)^\sigma. \end{aligned}$$

Per-period profits for firm- $i$ , given  $s_i z_i$ , are therefore;

$$\pi_i = \frac{(1 - \tau_i)^\sigma Y (s_i z_i)^{\sigma-1} (\sigma - 1)^{\sigma-1}}{w^{\sigma-1} \sigma^\sigma}. \quad (1)$$

Combining  $y_i$  above with the final-good production function results in the following expression;

$$w^\sigma = \left( \frac{\sigma - 1}{\sigma} \right)^\sigma \left[ \int_0^N (s_i z_i)^{\sigma-1} (1 - \tau_i)^{\sigma-1} di \right]^{\frac{\sigma}{\sigma-1}}. \quad (2)$$

Labor-market clearing results in;

$$w^\sigma = Y \left( \frac{\sigma - 1}{\sigma} \right)^\sigma \left[ \int_0^N (s_i z_i)^{\sigma-1} (1 - \tau_i)^\sigma di \right]. \quad (3)$$

Combining equations (2) and (3) and rearranging results in expressions for aggregate output and the wage rate;

$$Y = \left[ \int_0^N (s_i z_i)^{\sigma-1} \left( \frac{1 - \tau_i}{1 - \bar{\tau}} \right)^{\sigma-1} di \right]^{\frac{1}{\sigma-1}}, \quad (4)$$

$$w = (1 - \bar{\tau}) \left( \frac{\sigma - 1}{\sigma} \right) Y, \quad (5)$$

where  $(1 - \bar{\tau})$  is the weighted average of  $(1 - \tau_i)$  across all firms, weighted by each firm's share of aggregate output;

$$(1 - \bar{\tau}) = \frac{1}{N} \int_0^N \frac{P_i y_i}{Y} (1 - \tau_i) di.$$

We digress here to more precisely explain the counterfactual experiment we are interested in. In Figure 4 the curve labeled ‘low  $\gamma$ ’ represents the relationship between a firm's distortion  $\tau_i$  and productivity  $s_i z_i$  when  $\gamma$  is relatively low. In log scale, the slope of this curve is equal to  $\gamma$ , the elasticity of distortions with respect to productivity. To investigate the impact of more correlated distortions (a higher  $\gamma$ ), we increase  $\gamma$  and then compare the two steady state equilibriums. While an increase in  $\gamma$  must imply a pivoting of the curve in Figure 4, however, we must still choose a point to pivot around. Following Hsieh and Klenow (2009), we choose  $(1 - \bar{\tau})^{-1}$  as the pivot. This means that as  $\gamma$  is increased in our counterfactual,  $\bar{\tau}$  is kept constant. This allows us to focus on the effects of an increase in  $\gamma$  while abstracting from the (already well-studied) effects of a change in the average distortion.

Figure 4: Firm-Level Distortions and Productivity

Notice that aggregate output in equation (4) can be rewritten as;

$$Y = \left[ \int_0^N \left( s_i z_i \frac{\overline{MRPL}}{MRPL_i} \right)^{\sigma-1} di \right]^{\frac{1}{\sigma-1}}, \quad (6)$$

where a firm's revenue marginal product of labor and the average revenue marginal product of labor are defined as in Hsieh and Klenow (2009);

$$MRPL_i = \frac{P_i y_i}{\ell_i} \propto \frac{1}{(1 - \tau_i)},$$

$$\overline{MRPL} = \left[ \frac{1}{N} \int_0^N MRPL_i^{-1} \cdot \frac{P_i y_i}{Y} di \right]^{-1} \propto \frac{1}{(1 - \bar{\tau})}.$$

Equation (6) makes clear that if firm-level productivity were exogenous, removing misallocation by setting each firm's  $MRPL_i$  to  $\overline{MRPL}$  (bringing  $\gamma$  to zero while maintaining  $\bar{\tau}$ ) would have the same effect on aggregate output as in Hsieh and Klenow (2009), as long as the number of firms  $N$  is not affected. To see that  $N$  is indeed unaffected if productivity is exogenous, we use equations (1) and (2) to derive the expected per-period profits of an entrant;

$$E[\pi] = \frac{Y(\sigma - 1)^{\sigma-1}}{w^{\sigma-1}\sigma^\sigma} \left( \frac{1}{N} \int_0^N (s_i z_i)^{\sigma-1} (1 - \tau_i)^\sigma di \right) = \frac{Y(1 - \bar{\tau})}{\sigma N}. \quad (7)$$

As long as the cost of entry scales up with aggregate output (as it does here) and  $(1 - \bar{\tau})$  is not affected by the removal of misallocation (it is not), then equation (7) shows that the number of firms is independent of the extent of misallocation when productivity is exogenous.

To determine each firm's optimal productivity investment, we now take into account that  $(1 - \tau_i)$  is equal to  $(s_i z_i)^{-\gamma}$ . The value of entering for some firm  $i$  can be expressed as;

$$v_i = \frac{\mathbb{E}[\pi_i | s_i]}{1 - \rho} - c_S Y s_i^\theta - c_e Y,$$

or

$$v_i = \frac{Y(\sigma - 1)^{\sigma-1} s_i^{\sigma(1-\gamma)-1} \mathbb{E}[z_i^{\sigma(1-\gamma)-1}]}{(1 - \rho)w^{\sigma-1}\sigma^\sigma} - c_S Y s_i^\theta - c_e Y, \quad (8)$$

where  $\rho \equiv \frac{1-\lambda}{1+R}$ ,  $\lambda$  is the probability of firm death, and  $R$  is the real interest rate.

An entering firm will choose its productivity to maximize expected discounted profits. Given that all firms choose the same  $s$  in equilibrium, this results in the following condition;

$$c_S Y s^\theta = \frac{E[\pi]}{(1 - \rho)} \frac{[\sigma(1 - \gamma) - 1]}{\theta}. \quad (9)$$

Free entry guarantees the value of entry will be zero in equilibrium, resulting in the following free-entry condition;

$$\frac{E[\pi]}{(1 - \rho)} \frac{[\theta + 1 - \sigma(1 - \gamma)]}{\theta} = c_e Y. \quad (10)$$

Using equations (7), (9), and (10), we can now solve for aggregate investment in productivity (as a share of output), firm-level productivity, and the number of firms in a stationary equilibrium;

$$\lambda N c_S s^\theta = \frac{\lambda[\sigma(1 - \gamma) - 1](1 - \bar{\tau})}{\sigma\theta(1 - \rho)} \quad (11)$$

$$s = \left( \frac{c_e[\sigma(1 - \gamma) - 1]}{c_S[\theta + 1 - \sigma(1 - \gamma)]} \right)^{\frac{1}{\theta}} \quad (12)$$

$$N = \frac{[\theta + 1 - \sigma(1 - \gamma)](1 - \bar{\tau})}{c_e(1 - \rho)\sigma\theta}. \quad (13)$$

Equations (11) through (13) show that productivity and investment are decreasing in the elasticity of distortions with respect to productivity ( $\gamma$ ), whereas the number of firms is increasing in this elasticity. To gain intuition for these results, it is useful to first combine equations (7) and (9) to obtain an optimal investment condition expressing the optimal productivity  $s$  as a

function of both  $\gamma$  and the number of firms  $N$ ;

$$s = \left( \frac{[\sigma(1 - \gamma) - 1]}{c_S \sigma N (1 - \rho) \theta} \right)^{\frac{1}{\theta}}. \quad (14)$$

We now use equations (7) and (8) to create an alternative free-entry condition in order to show the value of  $s$  necessary to ensure the value of entry is equal to zero, given  $N$ ;

$$s = \left( \frac{1 - \bar{\tau}}{c_S \sigma N (1 - \rho)} - \frac{c_e}{c_S} \right)^{\frac{1}{\theta}}. \quad (15)$$

Both of the above conditions are represented in Figure 5, illustrating how  $s$  and  $N$  are obtained in equilibrium. As the elasticity of distortions with respect to productivity ( $\gamma$ ) is increased, the incentive to invest in productivity is reduced, shifting the investment curve down. This reduction in the investment of entrants increases the value of entry, given  $N$ . Free entry thus encourages a movement down and to the right along the free entry curve until the increase in the number of firms brings the value of entry back down to zero.

Figure 5: Firm-level Productivity ( $s$ ) and the Number of Firms ( $N$ ) in Equilibrium

Equations (11) and (13) also show both investment and the number of firms are decreasing in  $\bar{\tau}$ . The number of firms is also decreasing in the cost of entry  $c_e$ . These are common features of models with free entry, and reinforce the point that many of the policies often used to rationalize low productivity in poor countries should tend to *increase* the average size of firms.

Continue to consider our counter-factual exercise, wherein  $\gamma$  is increased while  $\bar{\tau}$  is held constant. The total impact of these more correlated distortions on aggregate output can be decomposed into effects working through the investment channel (which we focus on here) and the factor misallocation channel (the focus of Restuccia and Rogerson, 2008, and Hsieh and Klenow, 2009) in the following way;

$$Y = \underbrace{s(\gamma) \cdot N(\gamma)^{\frac{1}{\sigma-1}}}_{\text{investment channel}} \cdot \underbrace{\left[ \frac{1}{N} \int_0^N \left( z_i \cdot \frac{1 - \tau_i}{1 - \bar{\tau}} \right)^{\sigma-1} di \right]^{\frac{1}{\sigma-1}}}_{\text{factor misallocation channel}}. \quad (16)$$

As  $\gamma$  increases,  $\tau_i$  rises more quickly with productivity, so productive firms hire more labor and unproductive firms hire less. The impact of this less efficient allocation of labor is captured by the factor misallocation channel above. But a higher  $\gamma$  also leads to a decrease in firm-level productivity  $s$  and an increase in the number of firms  $N$ . The impact of these changes is captured by the investment channel. Note that if greater misallocation simply implied more dispersion in random idiosyncratic distortions (uncorrelated with productivity), then equations (11) and (13) imply that output would not be affected through the investment channel. This reinforces the finding of Restuccia and Rogerson (2008) that simple random dispersion in idiosyncratic distortions cannot explain much variation in aggregate TFP, and that the strength of correlated distortions (in this paper,  $\gamma$ ) is what generates the large potential impact from misallocation. In Restuccia and Rogerson more correlated distortions cause a reallocation of resources, increasing the output of unproductive establishments marginally while disproportionately decreasing the output of productive establishments (while leaving the equilibrium number of establishments unchanged). By incorporating endogenous entry and investment, we show here that more correlated distortions also reduce the marginal benefit of investing in productivity, thus reducing

establishment-level productivity and decreasing average employment across all establishments.

## 4 Quantitative Analysis

In this section, we calibrate the model to U.S. data and show the quantitative implications for establishment size, productivity, and aggregate output of hypothetical variations in the degree of correlated distortions across countries. We then use establishment-level data to estimate empirically the extent of correlated distortions across countries and their implications for cross-country variations in establishment size, productivity, and output. We end the section with a discussion of these results for variations in the model setup as well as some robustness checks on parameter values.

### 4.1 Calibration

We calibrate the model to manufacturing data for the United States in order to quantify the cross-country effects of correlated distortions on average establishment size, productivity, and aggregate output. The effects of distortions working through the investment channel depend on three key parameters in our model:

- $\theta$ : the elasticity of the investment cost function with respect to establishment productivity,
- $\gamma$ : the elasticity of gross distortions with respect to productivity,
- $\sigma$ : the elasticity of substitution between varieties.

In order to keep a close tie with the literature for comparison, we follow Hsieh and Klenow (2009, 2014) in setting  $\sigma = 3$ . For U.S. manufacturing, Hsieh and Klenow (2014) report  $\gamma_{US} = 0.09$ . The productivity elasticity of investment,  $\theta$ , plays a prominent role in determining the aggregate

share of output invested in productivity, along with the exit rate  $\lambda$ , the real interest rate  $R$ , and the average level of distortions  $\bar{\tau}$ . Given values for  $\lambda$ ,  $R$ , and  $\bar{\tau}$ , we choose a value for  $\theta$  to match U.S. manufacturing's share of value added invested in intangible capital, equal to 0.192.<sup>16</sup> We set  $\lambda$  and  $R$  equal to 0.1 and 0.05, standard values in the literature. Our value for  $\bar{\tau}$  is taken from the World Bank's Doing Business Surveys, which reports a tax rate as a share of output of 9 percent. Given each of these values, we use equation (11) to back out a value for  $\theta$  of 1.91. We note that this value for  $\theta$  is close to the value of 2.01 estimated using trade data in Rubini (2014).

The effect of distortions working through the output channel depends on the parameters above, as well as on the distribution of  $z$  (the exogenous component of productivity). In the model there is a mapping between  $z$  and employment, such that the demand for labor of establishment  $i$  relative to that of establishment  $j$  is;

$$\frac{\ell_i}{\ell_j} = \left( \frac{z_i}{z_j} \right)^{\sigma(1-\gamma)-1}.$$

Given values for  $\sigma$  and  $\gamma_{US}$ , we therefore use the above mapping to back out a distribution for  $z$  using data from the U.S. Census Bureau for the employment distribution of U.S. manufacturing establishments. Once we adjust the data to be representative of both paid and unpaid workers, we obtain a distribution of persons engaged per establishment ranging from 1 to 3,000 persons, and a distribution for  $z$  ranging from 1 to 102.<sup>17</sup>

---

<sup>16</sup>McGrattan and Prescott (2010) estimate that 13.5 percent of U.S. GDP is invested in technology and plant-specific intangible capital, but evidence from other countries suggests a higher investment share in manufacturing. Baldwin et al. (2009) report Canadian manufacturing's intangible investment as a share of value added is 1.42 times larger than the investment share of the entire economy. Assuming the same inflator for U.S. manufacturing generates an investment share of 19.2 percent.

<sup>17</sup>We transform the employment distribution into a distribution of persons engaged by assuming nonemployer establishments employ between 1 and 3 persons, while employer establishments with 1 to 4 employees are assumed to employ 3 to 5 persons. The employment data contain 10 employment ranges, and we assume establishment-level productivity is uniformly distributed within each range. The last range is open-ended (at least 1,000 employees), so we choose an upper bound of 3,000 to match an average employment size of 2,000 employees.

Using the above distribution and our calibrated parameter values, we quantify how average establishment size, investment, and output per capita (TFP) changes with the extent of correlated distortions, i.e., when  $\gamma$  is increased above the U.S. level (keeping other parameters constant). We follow Hsieh and Klenow (2009) in maintaining a constant average distortion  $\bar{\tau}$  as  $\gamma$  is increased. We report the results of this exercise in Table 2. The main finding is that the model implies large variations in average establishment size, productivity, and output per capita across economies with different correlated distortions.

Table 2: MODEL RESULTS ACROSS CORRELATED DISTORTIONS  $\gamma$

| $\gamma$                 | Establishment<br>Size | Establishment<br>Productivity | Productivity<br>Investment | Relative<br>Output |
|--------------------------|-----------------------|-------------------------------|----------------------------|--------------------|
| 0.09 ( $\gamma_{US}$ )   | 22                    | 1                             | 0.19                       | 1                  |
| 0.15                     | 11                    | 0.66                          | 0.17                       | 0.91               |
| 0.2                      | 7.8                   | 0.52                          | 0.16                       | 0.83               |
| 0.3                      | 4.9                   | 0.36                          | 0.12                       | 0.65               |
| 0.4                      | 3.6                   | 0.26                          | 0.09                       | 0.48               |
| 0.5 ( $\gamma_{India}$ ) | 2.8                   | 0.18                          | 0.06                       | 0.31               |

Notes: Columns report equilibrium values of average establishment size ( $1/N$ ), establishment productivity ( $s$ ), aggregate productivity investment over output, and aggregate output ( $Y$ ). Results in columns 2 and 4 are reported relative to the benchmark U.S. economy.

For instance, an economy with  $\gamma = 0.4$  features an average establishment size that is 17 percent of that in the United States. This economy also features an establishment-level productivity that is 26 percent of the benchmark due to lower investment in productivity (only 47 percent of that in the benchmark). As a result, output per capita is 48 percent of the benchmark economy. These are large differences in size and productivity compared to the findings in the broad literature on misallocation. The  $\gamma$ 's in Table 2 are hypothetical, but the range is plausible. As a point of reference, consider that Hsieh and Klenow (2014) report  $\gamma = 0.5$  for India. Given this value for  $\gamma$ , the model predicts an average establishment size of 2.8 workers, close to the value of 3.1 workers found in the data. The model also predicts India should have an aggregate output of about 31 percent of the U.S. level, generating a factor-difference in output about

twice that found between the U.S. and India in Hsieh and Klenow (2009).

It is important to note that the effects of correlated distortions on establishment size and productivity work solely through the investment channel, while the impact on aggregate output works through both the investment and output channels. In Table 3 we decompose this impact on aggregate output into the effects working through each channel. The effect of correlated distortions working through the investment channel are of a larger magnitude than that working through the output channel, and the difference in relative magnitudes is increasing in  $\gamma$ . Note that the impact of distortions working through the output channel for India is the same as that estimated for India by Hsieh and Klenow (2009), who use comprehensive micro data to back out distributions of distortions and productivity. We interpret this as suggesting that  $\gamma$  (the elasticity of distortions with respect to productivity) works well as a summary measure of correlated distortions.

Table 3: DECOMPOSITION ACROSS CORRELATED DISTORTIONS  $\gamma$

| $\gamma$                 | Investment<br>Channel | Output<br>Channel | Total<br>Impact |
|--------------------------|-----------------------|-------------------|-----------------|
| 0.09 ( $\gamma_{US}$ )   | 1                     | 1                 | 1               |
| 0.15                     | 0.93                  | 0.98              | 0.91            |
| 0.2                      | 0.87                  | 0.94              | 0.83            |
| 0.3                      | 0.76                  | 0.86              | 0.65            |
| 0.4                      | 0.64                  | 0.74              | 0.48            |
| 0.5 ( $\gamma_{India}$ ) | 0.50                  | 0.63              | 0.31            |

Notes: Columns 1 and 2 report the impact on aggregate output ( $Y$ ) of higher  $\gamma$ 's working separately through the investment and output channels. Column 3 reports the total impact. All results are relative to the benchmark U.S. economy.

We now compare our quantitative results to those in Hsieh and Klenow (2014). They model establishment-level investment over the life-cycle in the presence of correlated distortions and find that increasing  $\gamma$  from the U.S. level to that of India generates an increase in the number of establishments of only 14.3 percent, much less than the 87 percent we find here. Equation (13) above shows that the effect of  $\gamma$  on the number of establishments depends on two parameters,

the elasticity of substitution between intermediate goods  $\sigma$  (for which we use the same value as Hsieh and Klenow) and the elasticity of investment with respect to productivity  $\theta$ . We can therefore calculate the value of  $\theta$  necessary to generate a difference in the number of establishments between the U.S. and India of 14.3 percent. The necessary  $\theta$  is 10.3, much higher than our calibrated value of 1.91. To judge the reasonableness of these two values, note that equation (11) shows that aggregate investment in productivity also depends on  $\theta$ . While our value of  $\theta$  was obtained by matching U.S. manufacturing’s investment in intangible capital (19 percent), a  $\theta$  equal to 10.3 implies a much lower investment share of 3.6 percent. To see how implausibly low this share is, note that U.S. manufacturing’s investment in R&D (only one component of intangible capital) is 9.6 percent.<sup>18</sup>

## 4.2 Correlated Distortions

The calibrated model shows how correlated distortions encourage smaller establishments, lower aggregate output, and lower investment in productivity. In this section, we provide systematic evidence that the productivity elasticity of distortions is indeed higher in poor countries. We then provide evidence consistent with the mechanism highlighted in Section 3, using cross-country R&D data to show that aggregate investment in R&D is increasing in development, average establishment size, and the extent of correlated distortions.

Our measure of correlated distortions is constructed using establishment-level data from the World Bank’s Enterprise Surveys. Enterprise Surveys is an ongoing project of the World Bank to collect establishment-level data from mostly low and middle-income countries through face-to-face surveys. The dataset contains standardized information about sales, intermediate purchases, inputs, and a host of other variables for establishments in over 100 countries for at least

---

<sup>18</sup>U.S. manufacturing investment in R&D is from UNESCO. In calculating the investment share implied by  $\theta = 10.3$  we continue to assume  $\bar{\tau} = 0.09$ , as in our benchmark calibration. Alternatively, we can calculate the value of  $\bar{\tau}$  required to match U.S. manufacturing’s investment share, given  $\theta = 10.3$ . The required  $\bar{\tau}$  is an equally implausible -3.9, implying an average *subsidy* to establishment-level output of 390 percent.

one year since 2002. In each country, between 150 and more than 1000 establishments have been surveyed, and efforts have been made to make these samples representative of the population of establishments with at least five employees.<sup>19</sup> Importantly for our purposes, manufacturing establishments are classified into fifteen industries. From this dataset, we use observations containing values for industry classification, sales, number of employees, total wage bill, and purchases of materials and intermediate goods, for all countries which are also in our dataset (Section 2).

We back out our measure of establishment-level distortions and productivity for each establishment within a country-industry following Hsieh and Klenow (2009), except that we do not use capital data (more on this below). Abstracting from capital allows us to increase the number of usable countries substantially, as a large number of establishments in the Surveys do not report capital. From Section 3, labor productivity for some establishment  $i$  is;

$$\frac{P_i y_i}{\ell_i} = \frac{w}{(1 - \tau_i)} \left( \frac{\sigma}{\sigma - 1} \right) \propto \frac{1}{(1 - \tau_i)},$$

where  $P_i y_i$  is an establishment's value added (sales minus intermediate inputs) and  $\ell_i$  is employment.<sup>20</sup> As in Hsieh and Klenow, we remove the constant in the above expression by using labor productivity *relative to* the weighted average of labor productivity across all establishments within the same industry.<sup>21</sup> We infer an establishment's productivity  $sz_i$  by exploiting the following relationship;

$$sz_i = \frac{y_i}{\ell_i} \propto \frac{(P_i y_i)^{\frac{\sigma}{\sigma-1}}}{\ell_i}.$$

---

<sup>19</sup>Given the absence of very small establishments in the Enterprise Surveys data, we need to assume (as we do in Section 3) that the elasticity of distortions with respect to productivity is constant.

<sup>20</sup>Following Hsieh and Klenow (2009), we use an establishment's total wage bill (including benefits) in our computations instead of employment in order to control for differences in human capital across establishments.

<sup>21</sup>More precisely, we measure the distortion faced by firm  $i$  as;

$$\frac{P_i y_i}{\ell_i} \cdot \sum_{i'=1}^N \left( \frac{P_{i'} y_{i'}}{\ell_{i'}} \right)^{-1} \cdot \frac{P_{i'} y_{i'}}{\sum_{i'=1}^N P_{i'} y_{i'}}.$$

Productivity  $sz_i$  is similarly measured relative to  $\left( \sum_{i'=1}^N (sz_{i'})^{\sigma-1} \right)^{\frac{1}{\sigma-1}}$ .

With our measures of distortions and productivity in hand, we then do a simple OLS regression of logged distortions on logged productivity to obtain each country’s productivity elasticity of distortions.<sup>22</sup> Some countries have data for two or even three years, so we average elasticities over all years, weighting by the number of observations in each year. We obtain elasticities for 93 countries, 62 of which have establishment-size data.<sup>23</sup> Among these 62 countries, elasticities range from 0.22 to 0.74, averaging 0.52. Among all 93 countries the average elasticity remains a close 0.51. It is reassuring to note that our computed elasticity for India is 0.56, close to the value Hsieh and Klenow (2014) obtain using much more comprehensive micro data. To check the sensitivity of our measures to abstracting from capital, we also calculate elasticities using Hsieh and Klenow’s (2009) TFPR and TFPQ as our measures of distortions and productivity. Among the 50 countries which satisfy the criteria above, the average elasticity is 0.56. If we recalculate these elasticities abstracting from capital data (but only using observations that report capital) we find the same average, and the correlation between the two measures is 0.89.<sup>24</sup>

Figures 6 and 7 show how average establishment size and GDP per capita are related to the productivity elasticity of distortions in 63 countries (the elasticity for the U.S., 0.09, is taken from Hsieh and Klenow, 2014).<sup>25</sup> The data show a clear link between the elasticity and both average size and GDP per capita, consistent with the model.

---

<sup>22</sup>Before doing the regressions, we first trim the 1 percent tails of both distortions and productivity for each country to remove outliers. We then recalculate the averages as above.

<sup>23</sup>We do not use countries with fewer than 100 observations. Over the 62 countries with size data, we use a total of 37,410 establishment-level observations in our regressions.

<sup>24</sup>This is consistent with Gal (2013, Table 9), who calculates both labor productivity and TFPR for firms in a handful of OECD countries and reports correlations between the two statistics ranging from 0.8 to 0.9.

<sup>25</sup>The regression coefficients (standard errors) in Figures 6 and 7 are -1.94 (0.46) and -3.01 (0.80).

Figure 6: Establishment Size and Correlated Distortions

Figure 7: GDP per Capita and Correlated Distortions

In the model developed in Section 3, the mechanism through which correlated distortions reduce establishment size is the disincentive to invest in productivity. As a consequence, the model also predicts the share of output invested in productivity should be lower in economies with high  $\gamma$ . Broad measures of investment in intangible capital have not yet been collected for a large number of countries, but R&D intensity (one significant component of intangible capital

Figure 8: Establishment Size and R&D Intensity

investment) should provide a fair proxy. Figure 8 shows how establishment size across countries varies with R&D intensity, while Figure 9 shows how R&D intensity is related to  $\gamma$ .<sup>26</sup> Again using India as a point of reference, the model predicts an investment share in India about 29 percent of the U.S. level. In the data, India's R&D intensity is the same 29 percent of the U.S. level.

### 4.3 Discussion

Here we discuss our main results for reasonable extensions of the model and different values of key parameters.

**Model Extensions** In our baseline specification, the cost of entry and the investment cost of productivity are specified in units of aggregate output. Specifying both of these costs in units of labor dampens the effects of a higher  $\gamma$  very slightly. An economy with India's  $\gamma$ , for example, is predicted to have an establishment size of 2.9 workers per establishment, rather than the

<sup>26</sup>The regression coefficients (standard errors) in Figures 8 and 9 are 0.16 (0.04) and -4.23 (0.97). R&D data is taken from UNESCO, and is calculated as total investment in R&D as a share of GDP, relative to the U.S.

Figure 9: R&D Intensity and Correlated Distortions

baseline prediction of 2.8. Extending the model to include capital and capital accumulation does not change our results, as long as we interpret our baseline impact on aggregate output as an impact on TFP. The total impact on aggregate output would be magnified in the usual way through a change in the steady-state capital stock. Extending the model to allow entrants to learn the exogenous portion of their productivity ( $z$ ) before investing would generate a richer relationship between  $\gamma$  and the productivity distribution across establishments, as the incentive for more productive firms to invest more than less productive firms would be dampened. We leave this as an interesting topic for future theoretical and empirical research.

**Robustness on  $\theta$**  A critical parameter in determining the impact of correlated distortions on establishment size and output is the elasticity of investment in productivity  $\theta$ . We explore variations in the cross country implications of the model for two alternative specifications of  $\theta$ , 1.8 and 2.1. Recall that in the benchmark calibration  $\theta = 1.91$  to match an aggregate investment share of 19.2 percent. Note that these values for  $\theta$  could be obtained through our benchmark calibration strategy if we had used average distortions of  $\bar{\tau} = 0.14$  (for  $\theta = 1.8$ ) or  $\bar{\tau} = 0$  (for  $\theta = 2.1$ ). When  $\theta = 1.8$ , establishment size in the benchmark economy is 54 workers with an investment share of 20 percent, whereas when  $\theta = 2.1$ , establishment size

is 12 workers with an investment share of 17 percent. We report the results of variations in correlated distortions on establishment size, productivity, investment, and aggregate output in Table 4. While the cross-country implications of the model are sensitive to the value of  $\theta$ , for an empirically reasonable range, the model implies substantial negative effects of correlated distortions on establishment size and productivity.

Table 4: MODEL RESULTS ACROSS CORRELATED DISTORTIONS  $\gamma$

| $\gamma$                 | Establishment<br>Size | Establishment<br>Productivity | Productivity<br>Investment | Relative<br>Output |
|--------------------------|-----------------------|-------------------------------|----------------------------|--------------------|
| $\theta = 1.8$           |                       |                               |                            |                    |

Notes: Columns report equilibrium values of average establishment size ( $1/N$ ), establishment productivity ( $s$ ), aggregate productivity investment over output, and aggregate output ( $Y$ ). Results in columns 2 and 4 are reported relative to an economy with  $\gamma = \gamma_{US}$ .

**Robustness on  $\sigma$**  As in Hsieh and Klenow (2009), the impact of misallocation on aggregate output is increasing in  $\sigma$ , the elasticity of substitution between differentiated varieties. But assuming different values for  $\sigma$  is made complicated by the fact that  $\sigma$  determines the fraction of output allocated to entry costs, productivity investment, and taxes. In particular, a  $\sigma$  much higher than our benchmark of 3 cannot generate enough resources to cover investment (19.2 percent of aggregate output) and taxes (9 percent). However, McGrattan and Prescott (2010)

Table 5: MODEL RESULTS FOR DIFFERENT  $\sigma$ 'S

| $\sigma, \theta$           | Establishment<br>Size | Establishment<br>Productivity | Productivity<br>Investment | Relative<br>Output |
|----------------------------|-----------------------|-------------------------------|----------------------------|--------------------|
| $\sigma = 3 \theta = 1.91$ | 0.13                  | 0.18                          | 0.29                       | 0.31               |
| $\sigma = 5 \theta = 3.68$ | 0.04                  | 0.17                          | 0.04                       | 0.26               |

Notes: Columns report equilibrium values of average establishment size ( $1/N$ ), establishment productivity ( $s$ ), aggregate productivity investment over output, and aggregate output ( $Y$ ). Results are reported relative to an economy with  $\gamma = \gamma_{US}$  and  $size = size_{US}$ , with  $\theta$  and  $\gamma_{India}$  recalculated for each value of  $\sigma$  (see text for details).

estimate that investment for the entire U.S. economy is a lower 13.5 percent. We therefore recalibrate the model to match an investment share of 0.135 using a higher  $\sigma = 5$ , and interpret our results as the effects of correlated distortions on the entire economy.<sup>27</sup> Our recalibrated value for  $\theta$  is 3.68. In addition, assuming a higher value for  $\sigma$  generally increases the estimates of  $\gamma$  we obtain in Section 4.2, which will tend to increase the implied impact of observed misallocation. We therefore recalculate  $\gamma_{India}$  using  $\sigma = 5$  to get  $\gamma_{India} = 0.77$ . In Table 5 we report the estimated impact of misallocation in India relative to the United States with  $\sigma = 3$  (our benchmark) and with  $\sigma = 5$ . The net result is that the effect of misallocation in India on each variables is magnified when  $\sigma$  is increased.

## 5 Conclusion

Using a unique dataset of manufacturing establishments we construct from hundreds of sources, we documented a strong positive association between average establishment size and GDP per capita. The cross-country income elasticity of establishment size is 0.29 in our sample of 134 countries. We considered an otherwise standard model of heterogenous establishments with endogenous entry and investment in establishment productivity. We showed that a reasonably calibrated version of the model generates substantial differences in establishment size and

<sup>27</sup>Here we assume an average distortion of zero.

productivity across countries. These differences arise in the presence of correlated distortions which we construct and document across countries. Overall, the analysis in this paper puts us closer to understanding the patterns in operational scale and productivity observed across countries and over time.

Our analysis has abstracted from many factors which may be worth exploring further. For example, we have abstracted from different forms of entry and operation costs that seem to hinder the operation of firms in many poor countries. We have also abstracted from investment over the life-cycle of establishments which would generate a richer relationship between correlated distortions and the establishment-level productivity distribution. We leave a detailed exploration of these factors for future research.

## A Establishment Size Data

We describe in more detail how we construct the establishment size data. Our standardized definition of establishment size is the number of persons engaged per manufacturing establishment. Persons engaged is defined as the average number of persons working for an establishment, both paid and unpaid. A manufacturing establishment is defined as a physical location where the primary activity is manufacturing. Households are counted as an establishment only if signs are posted on the property indicating commercial activity. Not all countries report persons engaged or the number of establishments, so we also use data on the number of paid employees, the number of full-time equivalent employees, and the number of firms (collections of one or more establishments under common ownership).

The source data for each country is from economic censuses, as well as surveys which use comprehensive business registries to create sampling frames.<sup>28</sup> We use all publicly available data for the years 2000 through 2012.<sup>29</sup> In an effort to maintain consistency across countries, we do not use data unless efforts were made by a statistical agency to make the data representative of an economy's entire population of manufacturing establishments. We exclude any data collected without accounting for small establishments, except in cases where only establishments without paid employees are excluded. In the later case, we use U.S. data to adjust measured establishment size (this is the case for eight countries). Further, we include data for any country that excludes establishments with low revenue, as long as the revenue threshold is lower than the country's GDP per capita (this is the case for four countries). Two countries (Algeria and Honduras) do not report employment, but do report the distribution of establishments across multiple employment tranches. In these two cases we estimate total employment by using an average employment within each tranche consistent with data in comparable countries.<sup>30</sup> We

---

<sup>28</sup>For some countries data is from EUROSTAT or OECD's Structural Business Statistics, but we check each country's methodology to confirm the consistency of definitions.

<sup>29</sup>In some cases countries have published only press releases or bulletins describing the census data. We include these countries when the data meets our criteria.

<sup>30</sup>We assume average employment within a tranche to be one third of the distance from the lower to the upper threshold. For the last open-ended tranche (for example, 200 or more employees) we assume an average

are left with 134 countries with useable data for at least one year, with an average of six years per country.<sup>31</sup> Table 6 reports the total number of countries reporting each variable for at least one year, as well as the total number of poor countries and the total number of rich countries (defined as having GDP per capita below and above the median) doing the same.

Table 6: SAMPLE OF COUNTRIES

| Variable                 | Total Number<br>of Countries | Number of<br>Poor Countries | Number of<br>Rich Countries |
|--------------------------|------------------------------|-----------------------------|-----------------------------|
| persons engaged          | 101                          | 54                          | 47                          |
| employees                | 86                           | 34                          | 52                          |
| engaged and employees    | 53                           | 21                          | 32                          |
| full-time equivalents    | 25                           | 2                           | 23                          |
| establishments           | 83                           | 45                          | 38                          |
| firms                    | 67                           | 26                          | 41                          |
| establishments and firms | 16                           | 4                           | 12                          |

Note: ‘Poor’ and ‘Rich’ refer to countries with GDP per capita below and above the median.  
Data from multiple sources, see text for details.

We construct our standardized measure of establishment size (persons engaged per establishment) in the following way. First, we regress persons engaged on employees and full-time equivalent employees, as well as on employees and full-time equivalents separately. Second, country-years which report employees or full-time equivalents (or both) but lack measures of persons engaged are then assigned predicted values using the estimated coefficients from the above regressions. Third, predicted values for persons engaged per establishment are then assigned to country-years which report only firm-level data using the estimated coefficient from a regression of persons engaged per establishment on persons engaged per firm. Fourth, to standardize persons engaged per establishment in country-years which exclude non-employer establishments (this is the case for eight countries), we multiply these values by a factor equal to the average ratio of persons engaged per establishment to persons engaged per establishment with paid employees across all years in the U.S. (this ratio is 0.51). The same method is used to

---

employment equal to twice the lower threshold.

<sup>31</sup>Although size data is also available for Norfolk Island, it has been dropped for lack of any reliable measure of GDP per capita.

standardize data for five countries which report statistics for a combination of manufacturing, extraction, and energy (this ratio is 1.14). The results of the four regressions described above are;

- $\text{persons engaged} = 1.44 \cdot \text{employees} - 0.40 \cdot \text{full-time equivalents}$
- $\text{persons engaged} = 1.07 \cdot \text{employees}$
- $\text{persons engaged} = 1.12 \cdot \text{full-time equivalents}$
- $\text{persons engaged per establishment} = 0.89 \cdot \text{persons engaged per firm}$

In our final dataset, persons engaged per establishment is averaged over all years for each of the 134 countries.

Table 6 lists each country in the final dataset, the number of years for which data is available, and the sources from which data has been collected.

Table 7: LIST OF COUNTRIES AND SOURCES

| Country                | Code | Years | Sources                                                                                                                                                                                 |
